To sum up, there were 2 surgical deaths in 9 cases, and the total of deaths in the clinic was 5 (11 per cent.). For the surgical results in those cases in which *surgery became necessary we have to record our* thanks to Mr. W. H. C. Romanis, Mr. R. H. O. B. Robinson, and Mr. T. Holmes Sellors.

Conclusion

Hitherto the bronchoscope as an accessory in the treatment of lung abscess has not received its due in this country. The reason is not far to seek. The physician, who has the greatest interest in following these cases medically, has not had so far any experience with this instrument; the laryngologist has slight acquaintance with the lungs and no opportunity of following the disease, whilst the surgeon tends to prefer the knife. This is not surprising considering that our work has entailed 2000 bronchoscopies in the last four years.

We should lay it down as a dictum that every case of lung abscess should be watched and treated bronchoscopically so that if necessary operation may be undertaken at the optimum period. Each case must be considered with an open mind and enthusiasm for this method must not allow one to continue when experience has shown that open operation is desirable.

STRICTURE OF THE EXTERNAL URINARY MEATUS

By A. Ralph Thompson, Ch.M. Vict., F.R.C.S. Eng.
SURGEON IN CHARGE OF THE GENITO-URINARY DEPARTMENT AT GUY'S HOSPITAL, LONDON

An abnormally small external meatus is not uncommon, and I have, in my hospital notes, records of 70 cases of this nature. All these cases belong to the male sex and, although a similar condition is found in the female, I have not included in this series any cases occurring in women. By stricture is meant a narrowing of the external meatus, and such narrowings are well known to occur with hypospadias, and pinhole meatus, but with these two conditions the present paper is not concerned.

The causes acting in the production of a meatal stricture are fairly numerous. In the present series there are 33 patients of fifty-one years and over, and 32 between the ages of twenty-one and fifty, which indicates that this form of stricture commonly affects elderly and old men. In this connexion it cannot be doubted that the change in the condition of the penis in later life is to be taken into account. Thus the penis becomes smaller in middle and old age, and so the prepuce comes to cover the glans more completely than in younger people. In addition, the more prominent abdomen prevents the penis being seen, and it is less frequently washed than it used to be. Smegma is collected under the foreskin, and its retention may lead to considerable irritation; and as such a collection must be associated with the presence of organisms, inflammation may be produced, and fibrosis occur as a consequence. This fibrous tissue is developed under the mucous membrane near the meatus, which it throws into wrinkles, and so the meatus, instead of being a longitudinal slit with bilateral plaques, as it usually is, becomes circular and star-shaped.

The mucous membrane in chronic cases looks dry and scaly, but in recent cases the glans and meatus may appear "weepy." Both appearances are quite characteristic, and unlike gleet, the weepiness comes from the surface, not the inside of the urethra. The stricture is rarely as long as half an inch, and is often shorter. I have, however, notes of a case in which the stricture extended three or four inches up the urethra from the meatus.

The condition is one for which it is not difficult to indicate the treatment, but some cases are not so satisfactory as others in responding to treatment. Some seem to be cured, whilst others go on for a long time without showing a cure, though they may be much improved. Such strictures may produce precisely similar results as stricture occurring elsewhere, whether gonorrhœal or traumatic. Thus local perineal abscess may occur, also cystitis and stone in the bladder, ascending lymphatic infection leading to perinephritis, and septic nephritis. Meatal stricture must never be overlooked in connexion with the diagnosis of urinary obstruction and, indeed, it may be additional to the common causes of obstruction such as enlarged prostate or urethral stricture. The strictured area of the meatus may be very painful and tender, and the greatest tact and caution should be used even when a very small instrument is being used; we should always recollect that the meatal region is the sense organ of the bladder, and is the locality where the desire to micturate is felt. This tenderness and pain may be very conspicuous.

As meatal stricture occurs so often in old people it may be suggested here that such people should roll back the prepuce once a week and wash the glans and corona with warm water and soap; but some force is needed to get the smegma off the glans and away from the folds of the rolled back prepuce. The prepuce should always be replaced in position after such a washing.

The causes of the condition of meatal stricture may now be considered more fully. It is a little difficult to isolate the cause in a few of the cases, but generally speaking, the cases may be classified as follows: meatitis with advancing age; meatitis with or without phimosis in younger people; gonorrhœa; syphilis; after circumcision.

Meatitis with Advancing Age

The possible pathology of this condition has already been mentioned, but some of the cases give a history of gonorrhœa, and others have undoubtedly had this trouble, so that in certain cases gonorrhœa cannot be excluded as a possible cause, even in old people. The conditions which have already been described were present in all the types of stricture at present under consideration. The first case in my notes illustrates this point.

CASE 1.—Male, aged 70, had frequency and difficulty in completing the act of micturition. No appetite and great thirst; frequency of micturition at night. Gonorrhœa twice about fifty years ago. A stricture in the usual region manifested itself ten years later. The patient also had an enlarged prostate, and a definite stricture at the meatus, and at the first attendance no instruments were passed, owing to the difficulty of introducing even a small one, but when he next came a coudé catheter No. 8 was passed with some difficulty. A fortnight after this the patient reported that he was very much improved and was passing his water well. He was given malt and belladonna, and reported well a week later.

In this case the meatal stricture may have been gonorrhœal, and it certainly seems to have contributed to the urinary difficulties of which the patient complained. In the next case the stricture at the meatus was unaccompanied by any history of venereal disease, or evidence of another stricture, nor was there an enlarged prostate.

CASE 2.—Male, aged 61, complained of painful and difficult micturition. The pain was referred to the end of the penis. He was a long time in passing water, and it practically only dribbled. A meatal stricture was present, and only admitted a small probe. The stricture was dilated gradually and three weeks after the first attendance a metal bougie (No. 18/22 French size) could be passed easily. Yellow oxide of mercury ointment was used as a local application. Green iodide pills were also administered, not beause the case was considered to be one of syphilis, but because of the well-known antifibrotic effect of mercury and the iodides. The patient said he felt very well after this treatment, and at the end of two months was discharged with no sign of stricture.

It is recognised that hypospadias may be associated with a small opening, which though small has, as a rule, a perfectly healthy appearance, but in the succeeding case of hypospadias there may have been a good deal of fibrous tissue formed as a result of chronic irritation and inflammation.

CASE 3.—Male, aged 70, was admitted to out-patients with difficulty in micturition which had culminated quite recently in retention. A meatal opening was found after some difficulty, owing to the formation of scales and debris round the orifice due to chronic inflammation. The stricture was rapidly dilated up to No. 18/22 (French size) metal bougie. A fortnight after this it was noted that there was a hypospadias, and my house surgeon at the time, Mr. Le Vieux, now of Mauritius, slit the opening on its ventral aspect. I am not sure that I agree with this method of treatment, but the patient did very well and reported seven months later able to pass his water satisfactorily.

Attention has already been drawn to the value of mercury and iodides when accompanied with instrumentation, but in many cases the use of strychnine and digitalis will do much good as in the following case.

CASE 4.—Male, aged 70. He was said to have an enlarged prostate, but I could not agree with the diagnosis wholly. The meatus was very small, and he was using a catheter himself, as he could not pass any water without its aid. There was a thin purulent discharge from the meatus. It was not reported that there were gonococci in the specimen sent for examination, and the discharge itself was hardly of the character that one associates with gonorrhœa in old men. In my experience when old men get gonorrhœa they get it very badly. He was advised to continue his catheterisation as he lived in a distant part of Kent, and could not come regularly to the hospital. He was given liquor strychnine ♏ 2 and tincture of digitalis ♏ 2 three times a day before meals. Three months later he was seen in the genito-urinary department at Guy's Hospital, when he reported very well generally and locally.

I believe that these two drugs, by stimulating the bladder muscle, enable that organ to get rid of all its contents, which must allay the irritation due to stagnation of the urine in the bladder; but they must not be given unless the obstruction is overcome with instrumentation. I have found these two drugs most useful in similar cases.

Including these 2 cases, I have 18 cases of similar strictures occurring at the meatus, and associated with the conditions already described—viz., a diminishing penis, a lengthening of the prepuce, retention of smegma, and chronic irritation leading to fibrosis and the formation of a stricture at the meatus. The ages at which this condition manifested itself were 54, 55, 61, 66, 66, 69, 70, 70, 70, 71, 71, 72, 74 and 78, the average being 67. Clearly in some of these cases circumcision will do good, as in the following:—

CASE 5.—A male, aged 69, had phimosis with a meatal stricture. Circumcision was performed and the stricture was dilated. There was a completely successful result with which the patient expressed himself very pleased, though he had demurred when operation was suggested.

CASE 6.—Male, aged 71. There was eighteen months' history of difficulty in micturition in the standing position, but there was no difficulty when he was sitting down. (This sort of symptom is always worth noting, but I do not, at present, understand its significance.) Pain at the end of the penis occurred at the termination of micturition. Under the prepuce a good deal of thickening could be felt, but owing to the fibrosis the foreskin could not be retracted, and it was suggested that there might be a cancer. He was admitted into the hospital and circumcision was performed; no cancer was found, but there was much fibrosis round a small meatus, and after some difficulty a No. 6 (English) olive-headed catheter was introduced. This was not retained in position. Gradual dilatation followed and four months later No. 11 (English) catheter could be passed easily.

Sometimes the preputial orifice is so tight that urine may be collected between the prepuce and glans. If this happens it may produce a swelling which may be quite alarming to those who have not had much experience in these cases. The following history illustrates this.

CASE 7.—Male, aged 66, came to out-patients with a red irritating patch on the under surface of the glans. There was a history of one month's duration, and the foreskin was tight, and the glans harder than usual. There were a few enlarged glands in the inguinal regions. Circumcision was performed, and the patient did extremely well after the wound had healed and dilatation of the meatus had been performed. At the end of six months he was discharged. There was definite evidence that drops of urine had collected in this region, and perhaps had led to the redness and irritation. A similar case will be related later.

To make this series of cases more complete a case will now be quoted in which a meatal stricture may have been responsible for a fatal termination, with the common condition of ascending nephritis.

CASE 8.—Male, aged 71, with meatal stricture. He was recorded as a patient who would in all probability give little or no help to the surgeon, and when a student notices this kind of mental temperament it usually means that the patient is uræmic. The stricture was dilated, but his condition was so poor that he died in 12 days, having developed parotitis on both sides. At the autopsy it was found that he had a prostatic abscess, and pyelonephritis.

Of course everyone knows that prostatic abscess as a rule gives rise to urgent symptoms such as great pain and tenderness with pyrexia, but I have had three cases in which it did not do so, and they all died with septic nephritis. In this case the abscess in the prostate may have led to the ascending condition, and the meatal stricture may have had very little to do with it.

Meatal Stricture in Younger People

I now have a series of cases occurring at a younger age, in which there was little evidence of an acquired phimosis. The meatus was perfectly visible, but there certainly was a fibrotic condition of the meatus with a stricture. The first case is interesting in that a long after-history is known, and a possible cause can be assigned for the stricture. It is interesting also because a definite cure has been effected.

CASE 9.—Male, aged 44, was admitted to out-patients in August, 1919. He gave a history of a symptom which is very common—viz., dysuria at the beginning of the day, the flow becoming better during the day. He was treated with medicines, and omitted to attend till February, 1921. He then said he had passed two small stones per urethram, but there was no history indicating from which kidney they had come. He had a weeping meatus of a circular star shape, and a tight meatal stricture. The mucous membrane was puckered and thrown into folds, thus producing the star-shaped meatus. He had had both syphilis and gonorrhœa 30 years previously, and a strong positive Wassermann reaction was given. There was also a positive Kahn's reaction, but no other evidence of syphilis. Nor were there any signs of a chancre. There was no sign of any other stricture to indicate that the meatal stricture might have been gonorrhœal. If neither syphilis nor gonorrhœa had caused the stricture, it was possible that the passage of the stones, which was attended with some difficulty, might have started the process. At one time streptococci were found in the slight discharge from the meatus.

The patient was most regular in his attendance, and in nine months' time, after gradual and continued dilatation very gently performed, there was very little fibrosis round the meatus which resumed its normal shape and appearance. Later he was cured completely, but continued to attend as he developed neurasthenia. He is still coming to out-patients, after 13 years, and is a useful demonstration of a cured meatal stricture.

A second case may now be recorded, who has been attending for a long time, and even now can hardly be said to be "out of the wood."

CASE 10.—Male, aged 19. He came up first in May, 1929. He is an intelligent youth, and gave a history of dysuria for seven years. This commenced at the age of 12, a little young for a gonorrhœal stricture to develop. He had been dilated by a private doctor, and when he came first was using an instrument upon himself for the purpose of keeping the meatus open. The condition had improved slightly, but on the night before admission he could not pass the instrument. In accordance with my practice of never doing too much with a young man on his first appearance, he was given mercury and potassium iodide, and four days later an olive-headed bougie (No. 3 English) was passed. As the urethra was very tender, not much progress could be made. The patient was given hyoscyamus and buchu with an alkali, and at the beginning of July (six weeks after admission) a No. 6 olive-headed bougie was passed. Yellow oxide of mercury was used for lubrication of the instrument. There was still much pain and tenderness.

At the end of July he was admitted to hospital. The urethra was opened in the perineum, and the bladder was drained through the wound with a catheter "en demeure." After the wound had begun to granulate a laminaria tent was introduced into the meatus. On discharge there was a small fistula, which healed up very quickly, and this fact suggested that there was less obstruction at the meatus. The meatus remained large, but was not normal in appearance as in Case 9. It was patulous and circular, and appeared as though it were passive. The patient developed epididymitis, and this prevented dilatation being done as adequately as it might have been. Assiduous attention prevented the epididymitis going on to suppuration, and on Oct. 29th, 1929, Nos. 10, 11, and 12 (English) olive-headed bougies could be passed, though the last was very tight and caused a little bleeding. At the end of 1929 he was having a metal bougie (18/22 French) passed. After this he came regularly every fortnight, and an 18/22 metal bougie was passed every time. The pain was always great when an instrument was passed. The inside of the meatus was puckered and white as late as November, 1932. It is stated that the meatus was then dry, though it had been weeping before.

In this case I was never convinced that mercury and potassium iodide did any good in the way of relieving pain. The patient continued to attend, and at the end of 1934 internal urethrotomy was performed. He is certainly better, there is not so much pain, and the meatus is large, but there is still some fibrosis round it. This type of case is very difficult in its pathology and treatment.

The average age of this condition of meatitis without phimosis is thirty-one; the number of cases is 8, the youngest being nineteen and the oldest forty-three, so that the age is younger than that of the usual type of gonorrhœal stricture.

Meatal Stricture due to Gonorrhœa

The cases which are probably gonorrhœal in origin are more numerous and usually respond well to treatment. They are attributed to gonorrhœa because they all had a definite history of infection, and in many there was a definite stricture in the usual position of a gonorrhœal stricture; moreover, the ages of the patients were the usual age for gonorrhœal stricture. The cases number 17. The average age is forty-eight, the youngest being thirty and the oldest seventy-four. The first illustrative case is as follows:—

Case 11.—Male, aged 46. There were two strictures including the meatal one, and the history was complicated by attacks of malaria, and "influenza." The patient was said to have had eight attacks of the latter disease recently, but I have learnt to discount this diagnosis when urinary troubles are found; for example, cystitis may begin with general symptoms of fever and malaise, and any frequency is often considered part of the general illness. The patient had had gonorrhœa twenty-one years previous to admission. There was a stricture six inches up the urethra, and also a meatal stricture, with the note that there was an "india-rubbery" feeling of thickening round the meatus of one quarter of an inch long. This extended all round the meatus, and it was firm enough to prevent proper manœuvering with a metal instrument. A No. 1 (English) olive-headed bougie, "en baionette," was passed and tied in. In a patient with a history such as has been recorded the smaller the instrument which is passed the better for the patient, provided the route has been properly secured. This instrument was succeeded by a No. 5 (English) bougie at the end of three days, and later gradual dilatation was performed. During the succeeding eight months a No. 18/22 (French) metal bougie was passed regularly every fortnight.

This case is quoted, not because it is suggested that the meatal stricture was the great cause of difficulty, but because the stricture higher up was undoubtedly gonorrhœal, and for this reason the meatal stricture may be held to have a similar origin. The limitation of manœuvering with a metal instrument when there is a meatal stricture is important. Forcing of a meatal stricture causes much pain and may lead to spasm in the deeper parts, thus producing shock and faintness. Such a method of treatment should never be adopted even under an anæsthetic.

Two other cases may be recorded.

Case 12.—A male, aged 34, who probably had a gonorrhœal stricture in the region of the bulb, and also had a meatal stricture. The stricture was subjected to internal urethrotomy in hospital, and a few days after the operation a laminaria tent was used to dilate the meatal stricture. The patient responded to treatment very well and at the present time, five years after his admission, attends regularly, and a metal bougie (No. 18/22 (French) is passed every time.

Case 13.—A male, aged 54, had gonorrhœa at the age of 18, and had a stricture dilated at the Westminster Hospital. Later he came to see me at Guy's Hospital and undoubtedly had a stricture deep in the urethra; but the main difficulty lay at the meatus. The stricture at the meatus was dilated, and the patient attended for six years, a No. 18/22 (French) bougie being passed regularly and easily.

From my notes it would appear that these gonorrhœal strictures at the meatus give rise more frequently to incontinence and dribbling than to retention, although in cases of congenital pinhole meatus such an event is not uncommon.

Syphilitic Stricture of the Meatus

The next cause of meatal stricture is syphilis. The stricture is caused by a chancre which occurs at the meatus, probably complicated by sepsis, for a chancre elsewhere on the glans is not, in my experience, associated with much formation of fibrous tissue, though the old scar may be easily visible. But a chancre situated away from the meatus will not be subjected to the stream of passing urine. I have notes of 14 cases. The average age is forty-seven, the youngest being twenty-one and the oldest seventy-two. This age incidence is very much the same as that of gonorrhœal meatal strictures, and both differ markedly from that of the first class which, as we have seen, occurs in elderly and old men. Occasionally a chancre itself, whilst it is still active, will give rise to obstruction, but this is probably due to the temporary adhesion of opposed parts with dried serum, and debris.

Case 14.—Male, aged 28, came to out-patients with a history that for two days he had been unable to pass water. He not only had the sensation that there was something stopping the flow, but the tenderness was so great that he was also afraid to pass it. It is interesting to note that I recorded that the patient felt as though he had influenza, which is very significant in connexion with my previous remarks anent the diagnosis of influenza in what are really urinary cases.

The next case appears to show that the healing or partial healing of a chancre may lead to stricture very rapidly.

Case 15.—A male, aged 33, contracted syphilis, and on his admission stated that he had had a sore on the penis for a fortnight. The glans was œdematous, and it was noted that there were "bands on the glans." The meatus was minute, and only admitted with difficulty a No. 3 (English) olive-headed bougie. Novocain was applied, and the meatus slit on its ventral aspect. There was no other stricture. Appropriate remedies were prescribed in the way of drugs, and the patient was very much better when he ceased attending.

Case 16 is that of a male aged 35 who contracted syphilis at the age of 22, and was treated for chancre at the Lock Hospital. He had had four attacks of gonorrhœa, and there was a stricture in the region of the bulb. I very rarely come across cases of double stricture inside the urethra, so that the note that there were two strictures within three inches of the meatus was of importance, as the meatal stricture was associated with the presence of the scar of the old chancre. The presence of "bands" on the meatus had been noted already, and in one case it is reported that there is some growth of the mucous membrane over the meatus.

Case 17.—In this case the prepuce had become adherent over the glans, and offered so much obstruction to the passage of urine which had collected under it, that it had to be incised as the house surgeon was afraid of extravasation. There was also evidence of bladder retention, and such a stricture may lead to cystitis. Perhaps a little unlike the other cases of metal stricture, these meatal strictures due to chancre may be accompanied by retention of urine. This patient had been admitted to another hospital for retention, where nothing was done in the way of instrumentation, but the retention was apparently overcome by drugs and rest. He came to Guy's Hospital after his discharge from the other hospital, and the meatal stricture was gradually and continuously dilated. He was discharged able to pass his water well.

Healed chancres appear to cause worse strictures at the meatus than any other form of stricture there. One very bad case was the following :—

CASE 18.—A male, aged 72, was in a miserable condition with retention and overflow owing to fibrosis following the healing of a meatal chancre, to which caustic silver had been applied.

Another characteristic of these syphilitic strictures which are due to a chancre is the very great pain that accompanies them. In my notes frequent reference is made to this symptom, but fortunately mercury locally and by mouth affords one most efficient means of relieving it. I am not sure that mercury does much good in the other classes of meatal stricture, though I have seen it useful. It may be that this pain is an important factor in the production of retention, to which attention has been drawn.

Meatal Stricture following Circumcision

Finally, as cause of meatal stricture the operation of circumcision must be held responsible. I have in my notes reports of 4 such cases. I do not think that the operation had been badly performed, and perhaps the wound had become septic, but in two of the cases it is not possible to reject actual damage to the meatus as the chief cause. Careful attention by the operator should be paid to the actual locality of the meatus, and the glans under the foreskin which is being removed. Potassium bromide, grs. 5 every four hours, should be given to those who are beyond childhood before and after operation. A very light diet, and the prohibition of visitors of either sex for two or three days after the operation, would probably reduce even the small number of meatal strictures following circumcision. The age of all these 4 patients is just under nineteen, so that they are much younger than any of the other series of cases.

Conclusions

(1) Acquired strictures of the external urinary meatus are not rare. (2) They occur relatively frequently in old men, and may then be associated with a progressive phimosis, due to the diminution in size of the penis, the absence of proper cleanliness, and the collection of smegma. (3) In younger people chronic meatitis may occur with or without phimosis. This condition may lead to rather obstinate strictures. (4) Gonorrhœa occasionally produces meatal strictures. (5) Chancre may lead to a very painful form of stricture, and retention seems to be more common with chancre than with any other of the causes related here. (6) Stricture of the meatus occurs rarely after circumcision. (7) Stricture at the meatus yields, after a varying period of time, to instrumentation and the use of suitable drugs.

BRISTOL HOMŒOPATHIC HOSPITAL.—Mr. W. Melville Wills has given £10,000 to this hospital of which he is president. Mr. Wills bought the site and built the institution at a cost of nearly £150,000 as a memorial to his son. His donations now total about £180,000 towards capital endowments and expenditure, and he has given some £74,000 towards maintenance.

THE DIAGNOSIS OF ABNORMAL HIP CONDITIONS IN CHILDREN

BY M. FORRESTER-BROWN, M.D., M.S. Lond.
SENIOR VISITING SURGEON, BATH AND WESSEX ORTHOPÆDIC HOSPITAL AND COUNTY CLINICS ; HON. ORTHOPÆDIC SURGEON, EASTERN DISPENSARY, BATH, AND WALKER-DUNBAR HOSPITAL, BRISTOL

IT is a sound axiom that we shall never diagnose the presence of any condition of even moderate rarity unless we bear its possibility constantly in mind while we examine our patients ; also we shall make many unnecessary errors if we do not use a systematised scheme of examination. In preparing this paper I have attempted to meet these two requirements by making rough sketches of the pathological conditions which we are likely to meet in the hips of children, as demonstrated by X rays, and by reviewing the significance of the symptoms and signs which appear on routine clinical examination.

The Conditions Encountered

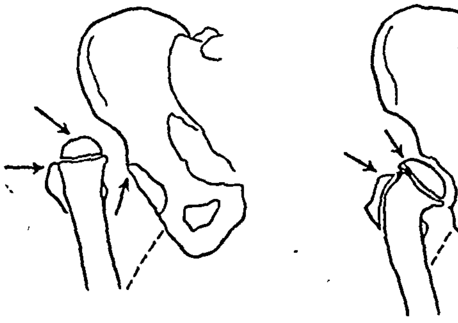
1. *Congenital dislocation of the hip* is really a faulty development of all the structures of the hip-joint, bones, cartilage, ligaments, and muscles, and is present at birth, though rarely recognised so early as is desirable. The radiographic diagnosis depends on noting whether the whole of the femoral head lies below the Y (triradiate) cartilage (Fig. 1).

2. *Rickety coxa vara*—i.e., bending of the neck of the femur and irregularity of the upper epiphysis—develops in early infancy, but the deformity may not be noted until, and may increase after, walking (Fig. 2). The most extreme deformation occurs when the condition is complicated by *congenital syphilis.*

3. *Coxa plana* is a lesion of the epiphyses of both femur and pelvis, thereby indirectly deforming the hip-joint (Fig. 3). It occurs from about the sixth year onward, but often is not recognised till several years from its onset, whose date is hard to determine, because different cases progress at very varied rates, while the early symptoms are vague. As the initial deformity tends slowly to increase, cases are sometimes first brought for treatment during puberty. If they are brought at the onset, the X ray signs may be entirely absent and the diagnosis is only clear after some months, when the radiogram is apt to demonstrate changes occurring in the course of the most thorough treatment. The condition was described almost simultaneously by Calvé, Legg, and Perthes, whose names have been attached to it, while the earliest description by Waldenström of Stockholm is overlooked, because he called it tuberculous ; yet double cases may have one side become tuberculous, and cases of undoubted tuberculosis may end with X ray appearances indistinguishable from it. In other words, its primary cause is still undiscovered and may not be a single factor. The characteristic features are flattening of the femoral head, preceded by " fragmentation " of its structure and followed by shortening of the neck and opening-out of the acetabulum.

4. *Slipping of the upper epiphysis* of the femur (or rather of the shaft upward on the neck) usually develops during adolescence, especially in the flabby, over-weight child, whose appearance suggests endocrine disturbance, who may have lowered sugar tolerance, partial gigantism, and weakening of other bones, such as the tibia and femur at the knee, giving severe knocking. The head for a time keeps its

normal shape and situation; the neck slips upward (Fig. 4). The infantile type of slipped epiphysis is usually overlooked till puberty, when increase of height and weight make conspicuous the mechanical strain on the hip-muscles by producing a waddling gait. The deformity is a great exaggeration of the slipping that first occurs at puberty; it has been described in infants, and I have seen a severe case in a child five years old, in which the condition was irreducible by manipulation.

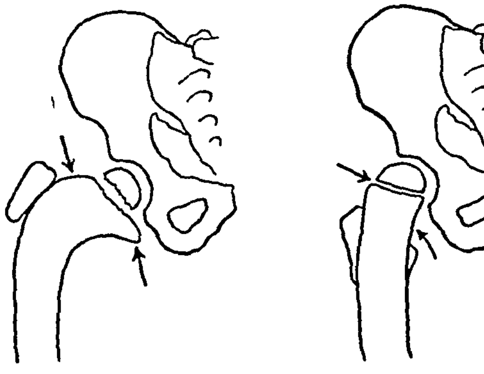


Dislocation (with coxa valga). *Subluxation* (with coxa vara).

FIG. 1.—Dislocation and subluxation.

5. *Coxa valga*—i.e., overgrowth of the neck of the femur with loss of the normal angle, so that neck and shaft run almost in one line—may be a result of infantile rickets, or develop as a growth abnormality in tall children (Fig. 2).

6. *Tuberculosis of the hip* (or neighbouring bones) has been left thus far on the list, because, though it is usually the first diagnosis made in a child that complains of the hip region, it is, in the area where I practise, one of the rarer causes. This is fortunate, because its treatment is infinitely tedious, even in early cases, and its result in the best hands is nearly always a stiff hip. Fig. 5 is a composite picture of three early types, which, as shown by the drawing on the right, are nearly always combined in the late stages. There may be a focus in the under surface of the neck of the femur, or in the roof of the acetabulum, both extra-articular at the start, or a pure synovial lesion. Each of these may and usually does spread to neighbouring parts and all that treatment can do is to limit the spread by reduction of strain and by stimulating a layer of calcification to form a limiting barrier all round.



Coxa vara. Coxa valga.

FIG. 2.—Coxa vara and valga due to rickets.

7. *Non-tuberculous arthritis* of the hip is of many types. The rheumatoid type, like Still's disease, seldom seems to begin in a single hip, but is usually symmetrical and usually is first noticed in the knees and ankles, though the hips may be affected simultaneously. There is a syphilitic type in which the metaphyses, and, or epiphyses, are diseased as well as the joints. It is the X ray appearances and other clinical signs such as depressed bridge of the nose which are characteristic.

Arthritis of true rheumatic origin, less acute than rheumatic fever and another of quite unknown origin, are probably the commonest causes of hip symptoms in children. As they clear up after recumbency for a few weeks or months and leave no radiographic traces of their presence, it is hard to gain knowledge of the causes. It is probable that the majority of so-called tuberculous hips which healed in the past with very little splinting or recumbency were of this nature. Those who wish to claim credit for their successful termination can still call them very early tuberculosis, and no one is in a position to dispute the diagnosis, except in such as give a negative Mantoux test to high concentrations of tuberculin.

8. *Osteomyelitis* of the upper end of the femur of pyogenic origin is apt to simulate arthritis of the joint and probably is associated with fluid in the hip, even if this contains toxins rather than organisms.

9. *Purpura with hæmorrhage into the joint*, or under the periosteum in the neighbourhood, also simulates acute arthritis and must be diagnosed by the presence of subcutaneous and other hæmorrhages elsewhere or by the characteristic transverse line of dense calcification across the metaphyses of the chief long bones. Sometimes the pre-operative diagnosis is impossible.

Clinical Picture

HISTORY

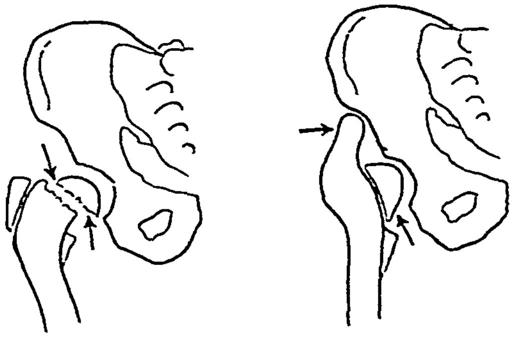
The history of hip conditions in children is seldom very enlightening and sometimes positively misleading. Thus there is usually a history of *injury*. Now, though this may have been the factor which localised an infection, yet as all children are constantly damaging themselves, it is more likely that the parent has merely recalled some insignificant fall in order to associate it with the disease. *Pain* also is misleading as it is often referred to the knee rather than the hip.

The *duration of the symptoms*, as noted by the parents, is apt to be equally misleading, for it depends entirely on their attention and powers of observation, both of which are often limited. Thus when a radiogram demonstrates a dislocation, which must have been present at birth, the mother may assert most emphatically that the child only limped from the age of four years; because it was then she expected it to acquire proper balance, and the failure of this attracted her notice. Sometimes the X ray shows destruction of the head of the femur by a slow disease like tuberculosis; yet the parents say the child only limped for a week.

Symptoms which are of value are *night-cries* and *night-sweats*, and *shrieking* when the child is bathed or handled: but they do not differentiate between an inflamed joint and the tender muscles of acute poliomyelitis. Loss of weight and loss of appetite in a previously healthy child are of importance; yet many children are constantly pernickety over food without definite cause. Complete giving-way of a limb or *inability to walk* of a child who has previously walked well may represent many causes, from sudden paralysis to severe pain of any kind.

EXAMINATION OF THE PATIENT

Two precautions are essential, and a third desirable, in the physical examination of the child.



Adolescent. Infantile type.

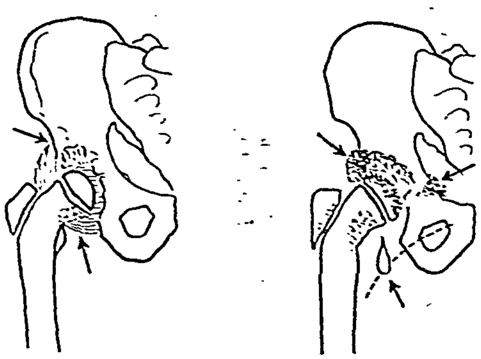
FIG. 4.—Slipped epiphysis.

1. To strip him completely. No obscure hip condition will be spotted by looking between the half-lowered trousers and the half-raised shirt.
2. To get him to walk and carry out voluntary movements *before* a hand is laid on him which may start pain.
3. To have him walk along a straight line, such as a strip of carpet, to a definite objective, such as a mirror, which latter should be fitted in every clinic and out-patient department.

1. *Gait.*—If the child is able to walk he may sway over to the affected hip at every step. This has two possible interpretations: (*a*) a reflex effort to reduce the grinding movement on inflamed cartilage, so that it is present in very early stages of tuberculosis of the hip, when patients do not keep off the bad hip, and also in coxa plana; (*b*) to reduce the mechanical strain on weak muscles, so that it is common in the slightest degree of paralysis of the glutei (the throw being backward when the gluteus maximus extensor of hip is involved) or when the tension of the abductors is upset by raising of the great trochanter, through dislocations and bending of the femoral neck.

2. *Lordosis* (hollow-back) may be the result of such a gluteal weakness, or may be a mechanical compensation for fixed flexion of one or both hips, whether permanent, or only from muscle-spasm. It is very conspicuous in dislocation cases, because the glutei have lost their fulcrum and the whole pelvis tips forward. The shoulders are thrown far back to keep the centre of gravity over the feet.

3. *One heel raised* from the ground may be due to organic shortening of the tendo Achillis from many causes, or from the effort to keep the pelvis level in spite of a short leg. In the former case, even if some shortening exists, it is rarely equivalent to the equinus, so that the affected side of the pelvis tips up. Actual shortening may be permanent ("true") from defective growth, or bone destruction secondary to many causes, or temporary ("apparent") from spasm of the hip-flexors and adductors (Fig. 6). Thus the spastic hemiplegia, the neglected poliomyelitis with foot-drop, the early tuberculous hip with spasm and the late tuberculous hip with bone destruction may all have this swaying gait with lordosis and one heel off the ground.



Early. Late.

FIG. 5.—Tuberculosis.

4. The power to *balance on one leg* may throw further light on the cause. If the heel now comes to the ground, one may know the equinus attitude is compensatory to shortening, or the spasticity slight. If the patient can stand quite or almost unsupported, but the shoulders are thrown still further over the affected limb, one can exclude dislocation and diagnose severe muscle-weakness (various causes). Dislocation is demonstrated by *Trendelenburg's sign* of dropping of the whole pelvis on the femur, so that the sound side falls instead of rising. A mild degree of this seems to occur in tall flabby children, in whom the only defect revealed by X rays is coxa valga with the neck of the femur two or more inches long.

5. The *recumbent attitude* should next be observed, or first in children too young, or too ill to walk.

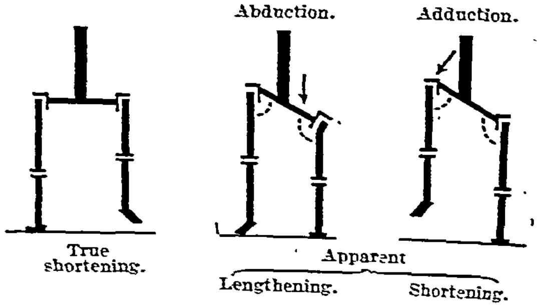


FIG. 6.—Shortening, true and apparent.

Falling outward of the foot on the affected side is common in hip abnormalities. It may be due to spasm in the very earliest stage of tubercle or other synovitis of the hip; or due to the weight of the limb in dislocations; or to shortening of the unopposed sartorius in poliomyelitis of the hip-muscles; or to twisting of the neck of the femur in rickets and slipped epiphysis. Young infants tend to lie with the lower limbs symmetrically placed and most commonly with the feet pointing inward; therefore if one foot constantly lies on its outer side while the other does not, the attitude is very suggestive of congenital dislocation, especially in the absence of any discomfort, and a radiogram should be taken at once to exclude this serious deformity, whose treatment cannot be started too young.

Asymmetry of the skin-folds on the inner sides of the thighs in very young, fat infants is very suggestive of dislocation and is another indication for radiography, which is the only certain means of making the diagnosis at the age when it is most valuable.

Raising of one patella above the other, when the infant is lying relaxed, is a better guide to shortening than measurements, which are hard to take in a fat wriggling infant. Naturally, these two signs are absent in double congenital dislocation.

Projection of one or both great trochanters (the "adult female outline") is a valuable sign to look for with the infant flat on its back. Unilateral projection and shortening of the distance to the pelvic crest proves some lesion between the trochanter and pelvis, which may be: dislocation of the head from the acetabulum, congenital, or inflammatory; bending of the neck, or slipping between head and neck; destruction of head, or neck, or both.

Lordosis, so that a hand may be slipped easily under the lumbar region, suggests fixed flexion of at least one hip.

6. *Measurements of the limbs* should be undertaken before the joints are disturbed, for they are difficult to obtain once the patient struggles. Most hip conditions are associated with wasting of the thigh muscles and much slighter, if any, wasting of the calf muscles. Considerable wasting of the latter, especially if associated with wasting of the thigh on the opposite side to the limp, is very suggestive of poliomyelitis. After paralysis has been excluded, the thigh and gluteal wasting associated with severe tuberculosis are much more marked than with any of the other hip conditions referred to, but early tuberculosis may show very little wasting. The thigh is most easily measured by running the tape a definite number of inches above the patella, so as to reach near the middle of the thigh, and then encircling the limb. Measurements below the middle are over tendons and may show little variation from the normal.

Great inequality of two limbs, which have a full range in all joints and no muscle weakness whatever, represents a form of local gigantism, of obscure origin, its only significance being the risk of severe scoliosis from unequal length of the limbs.

In measuring shortening, it is essential to have someone fix the pelvis, so that the line joining the two anterior superior spines is transverse to the body-axis, as slight tilting of the pelvis gives apparent shortening of a limb. After the true shortening has been ascertained it is useful to measure from the umbilicus to each internal malleolus, which gives the apparent shortening from flexion and adduction of the hip.

7. *The range of the hip-joints* to passive movements may now be tested. Flexion is the one which causes least pain and should be done first, beginning with the unaffected limb; when this knee is on the chest, it should be noted whether the affected thigh rises from the table, which indicates fixed flexion of that hip. As already remarked, the cause of such flexion may be actual bone change, or only flexor spasm in early joint disease, in early and late poliomyelitis, and in spastic paralysis. The angle should be carefully recorded for future reference, as it provides one of the most valuable guides to progress. When each hip has been flexed in turn, both should be brought up together and externally rotated (frog-position). If a hollow is seen in the groin, where the head of the femur should lie, it is very suggestive of dislocation.

Abduction of the hips is limited in most hip abnormalities; the shortening of the adductors may be developmental, as in congenital dislocation, spasm as in spastic paralysis, or protective in inflamed conditions of the joint. Adjacent inflammation, such as osteomyelitis and early extra-articular tuberculosis, does not show much adductor spasm, though a little flexor spasm may be associated with them. Inflamed glands and appendicitis and kidney inflammation are other causes of spasm of the hip flexors.

External rotation is reduced only in severe arthritis, whereas internal rotation is reduced early in tuberculosis and coxa plana, and its return is late and is one of the signs of complete recovery. Lesions of the neck of the femur, also dislocations, throw the limb into marked external rotation.

8. *Palpation of the hip* region should be reserved for the end of the examination, as it is likely to bring out pain in inflammatory conditions or to irritate a nervous child.

The great trochanter should first be felt and, if it is raised on one side above the other, as already noted, the lesion is between it and the pelvis. If it lies very far back, one has anteversion of the neck, which is common in congenital dislocation. While the fingers of one hand lie along the outer side of shaft and great trochanter, its thumb should be placed below the middle of Poupart's ligament and an attempt made to compress the femoral artery over the head. If the artery disappears into a soft bed of muscle, one knows the head is dislocated and then one must feel round with the thumb for it, while the second hand grasps the knee and gently rotates the limb. If this moves the head just below the anterior superior spine, one is dealing with an anterior dislocation. If the head is not there, carry the child's knee across its chest and feel on the outer face of ilium under the glutei, where the head, in cases of posterior dislocation, can be made to project under the skin.

Tenderness over a normally situated head is suggestive of arthritis, though it may occur in coxa plana. In severe cases pain, similar to that which occurs spontaneously, can be induced by jarring the great trochanter or the heel. It should be emphasised that the absence of these signs and of limitation of movement in all directions does not exclude early tuberculosis of the joint. As already pointed out the lesion is so apt to start extra-articularly, that if one waits for the signs of acute arthritis, one will be waiting for unnecessary bone destruction. Any case with muscle spasm and tenderness in the region of the hip should be treated with the same thoroughness as a frank tuberculosis until all signs and symptoms have disappeared. It is with tuberculous hip, as with other orthopædic conditions, that, though attempts at early diagnosis and treatment improve the average results, yet they by no means simplify the work of the surgeon, nor reduce the total burden on a hospital; for they involve the special treatment of many cases which might have recovered with casual treatment at home.

9. Finally, let us not despise the help of the laboratories, the Wassermann, the blood-sugar and sugar-tolerance tests, and the Mantoux test. Of it, as of older tuberculin tests, it seems true that a positive in an infant is strongly suggestive of active tuberculosis; while a negative in an adolescent almost excludes tuberculosis of the hip, where other signs are doubtful. The converse is not true.

EFFECT OF TREATMENT

Treatment is not included in the scope of this paper, but it must be remarked that sometimes the effect of adequate splinting in recumbency provides the final essential diagnostic test. Certainly, no abnormality of the hip region in a child should be regarded lightly, nor should it be watched except in a first-class hospital. In the past too many congenital hips were watched till they were irreducible, because "the limp was not getting worse"; too many tuberculous hips have developed gross deformity, because radiography with a poor apparatus or a poor technique "showed a "normal joint." Therefore it is safe to say that the diagnosis as well as the treatment of hip abnormalities in children demands first-class nursing, prolonged and constant observation, and first-class radiograms interpreted by an expert. Nobody who fails to command these facilities should undertake the serious responsibility of keeping a hip patient out of an orthopædic hospital.

INDUCED WATER RETENTION IN DIAGNOSIS OF IDIOPATHIC EPILEPSY

By J. L. Clegg, M.B. Liverp., D.P.H., D.P.M.
ASSISTANT MEDICAL OFFICER, SOUTH YORKS MENTAL HOSPITAL, MIDDLEWOOD, SHEFFIELD ; AND

F. T. Thorpe, M.R.C.S. Eng., D.P.M.
PATHOLOGIST AND ASSISTANT MEDICAL OFFICER AT THE HOSPITAL

After the exclusion of other causes of seizures, there remain cases in which the differential diagnosis between idiopathic epilepsy and hysteria can be made only when an actual fit has been witnessed by a trained observer. This may prove a difficulty when the fits are infrequent, even though the patient is detained in hospital for this purpose.

Jacobsen[1] has proposed a test to establish the diagnosis of epilepsy in the shortest possible time. It is founded on the theory that retention of water in the body will precipitate a fit in predisposed persons. To induce a positive water balance he administered large quantities of water by the mouth, accompanied by hypodermic injections of Pitressin. This is the pressor and antidiuretic principle of the posterior lobe of the pituitary body, as distinct from the oxytocic, and has the property of causing water retention in normal individuals. It also causes a slowing of the pulse, and stimulates the involuntary muscle of the alimentary and genito-urinary tracts. An increase in the body-weight of from 3 to 6 per cent. was taken as an indication that a positive water balance had been produced.

Jacobsen tested some 40 patients in this way, mainly children, and found that a fit occurred in all his epileptics once the water balance had been rendered positive. The only failures he had were with a few epileptics in whom a positive water balance could not be induced and in two patients who became nauseated, so that the test was discontinued. A series of normal controls tested in a similar manner had no fits; nor did the epileptics have them when they received pitressin alone or water alone.

PRESENT INVESTIGATION

We have repeated Jacobsen's procedure in 16 adult epileptics and 7 non-epileptic controls. Our object has been to confirm his results, or otherwise, and further to see whether any changes in the osmotic pressure of the blood accompany the water retention. The epileptics tested were patients who had fits relatively seldom. They were kept in bed during the investigation; ordinary diet was taken, and in cases where Luminal had previously been administered it was continued. At the beginning of the test the bowels were opened by an enema, the patient passed urine, and the weight was taken. An injection of 0·25 c.cm. of pitressin was then given hypodermically, along with 300 c.cm. of water by the mouth. Subsequently water was given by the mouth in amounts of 300 c.cm. every two hours, and hypodermic injections of 0·5 c.cm. pitressin every four hours, until ten injections had been given. If a fit occurred before this, no further water or pitressin was administered. In the latter event ordinary diet was stopped and 5 oz. cream was given four-hourly until the fits ceased. The patient was weighed every four hours, and all the urine passed was measured.

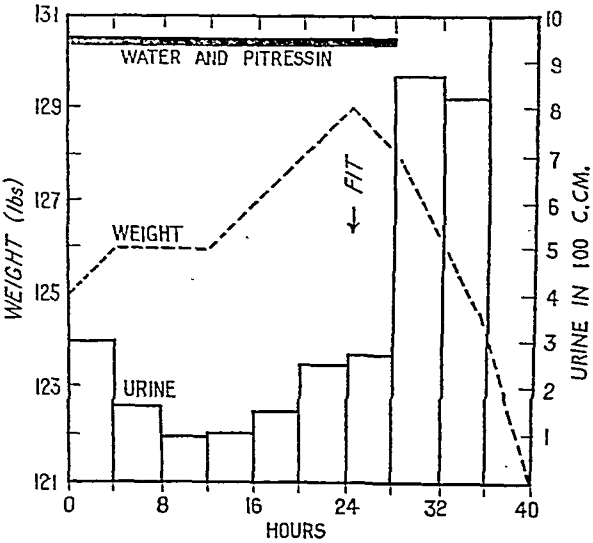

FIG. 1.—Results of a test showing increase in weight during administration of water and pitressin, followed by a fit.

Pallor followed the administration of pitressin in each case; it usually became noticeable about five minutes after injection and lasted up to two hours. It was accompanied by slowing of the pulse, but there was no marked alteration in the blood pressure. After two or three injections the action of the drug on the intestinal muscle was shown by slight looseness of the bowels. In all the cases the excretion of urine was diminished, and in one patient suffering from chronic nephritis considerable œdema of the ankles and face was produced. No œdema developed in any of the other cases, and it would appear that this condition constitutes a definite contra-indication to the carrying out of the test.

Table showing Results of Water Retention Test

Case.	Fits per year.	Pitressin and water.	Case.	Fits per year.	Pitressin and water.
1	41	+	9	25	+
2	18	+	10	26	+
3	8	+	11	3	+
4	17	+	12	3	+
5	5	+	13	3	Suspended.
6	16	+	14	1 in 2 yrs.	—
7	31	+	15	1 ,, 5 ,,	Suspended.
8	3	+	16	1 ,,10 ,,	—

+ = one or more fits. — = no fit.
Pitressin administered alone } = no fit.
Water ,, ,, }

Fig. 1 illustrates a typical case. There was a progressive increase in the body-weight during the administration of pitressin and water, with a definite drop when it was discontinued. The excretion of urine was affected conversely. A fit occurred after the weight had increased by 4 lb.

The accompanying Table shows that of the 16 epileptics tested. 12 had one or more fits during the administration of pitressin in combination with water. In 2 of the 4 negative cases, the test had to be discontinued because of hiccup and vomiting. The other 2 were both cases in which the fits were normally very infrequent. In none of the 7 controls was a fit induced by pitressin and water, nor in any of the epileptics to whom water or pitressin was administered alone.

CRYOSCOPIC ESTIMATIONS

The osmotic pressure of the blood depends on its molecular concentration, which can be accurately determined by the estimation of the freezing-point. Any retention of water in the blood stream will consequently be shown by an elevation of the freezing-point, provided that the retention is not compensated, from an osmotic standpoint, by simultaneous retention of urinary solids.

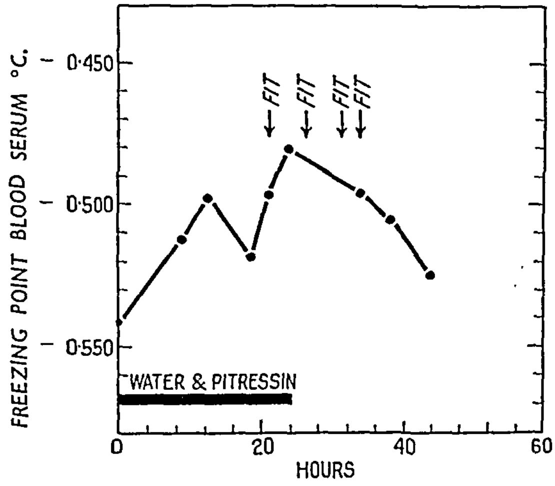

FIG. 2.—Freezing-point of blood-serum in relation to fits induced by administration of water and pitressin.

According to Margaria [2] the average freezing-point of the blood is −0·553° C., and under normal conditions remains remarkably constant. Water-drinking is normally followed by prompt diuresis and there is only a slight reduction of the freezing-point, the excess fluid being readily taken up in the tissue spaces of the muscles. But when water is taken during the antidiuretic action of posterior pituitary lobe extract, Fremont-Smith [3] and others have shown that an appreciable dilution of the blood takes place, which is followed by a similar dilution of the cerebro-spinal fluid. We therefore thought it would be of interest to estimate the freezing-point of the blood-serum of our epileptics in order to determine the change in osmotic pressure at the time of production of the fit.

The apparatus used was the Beckmann-Heidenhain cryoscope, and the usual precautions were observed with regard to the temperature of the cooling bath, the amount of supercooling, and the uniformity of stirring, which was carried out by hand. Solidification was induced by the introduction of a small crystal of snow. Specimens of blood obtained by vein puncture were centrifuged, and the serum kept under oil until the estimations were made.

A preliminary investigation was carried out on 3 epileptics by estimating the freezing-point at the beginning of the test, and immediately after the production of a fit. In these cases there was an elevation amounting to 0·039, 0·054, and 0·060° C. Samples of blood were then taken at intervals throughout the test, and in 3 epileptics a freezing-point curve was obtained which showed a progressive lowering of the osmotic pressure of the blood more or less in proportion to the quantity of water ingested and the increase in body-weight. Fig. 2 illustrates the type of curve obtained, which shows that at the time the fits occurred there was a considerable disturbance of the osmotic regulation of the tissues. Experimental water intoxication in animals results in retching, vomiting, and violent convulsions, but it must be remembered that epileptic phenomena are more readily produced in animals than in man.

The epileptic appears to have an unstable nervous system which is hypersensitive to sudden changes in the osmotic pressure of its tissue fluids, and in the above test the fit may represent a reaction to the inflow of water into the cerebral tissues.

CONCLUSIONS

This test for idiopathic epilepsy is of definite value in arriving at a diagnosis in doubtful cases. No fit may be induced, however, when the patient has them very infrequently, and therefore a negative result is not absolutely conclusive. The water retention is accompanied by marked lowering of the osmotic pressure of the blood-serum, and it is probable that the resulting exudation of fluid into the nervous tissues is the precipitating factor in production of the seizures.

We wish to express our thanks to Dr. A. Pool, medical superintendent of the South Yorkshire Mental Hospital, for his helpful advice; also to Nurses Russell, Platts, Robinson, Wingfield, and Norton, for the care with which they carried out the technique.

A NOTE ON THE
BLOOD CHEMISTRY IN EPILEPSY

BY ROY T. FLETCHER,* M.B. Glasg.

AND

OLIVE D. PEDEN,† B.Sc.

(From the Department of Pædiatrics, Glasgow University, and Biochemical Laboratory, Royal Hospital for Sick Children, Glasgow, and Gartloch Hospital, Gartcosh)

THE relationship between epileptic seizures and the amount and distribution of water in the tissues and tissue spaces has been stressed during the past few years. The work of McQuarrie and his colleagues [1] and other workers appears to indicate that the beneficial effect of ketogenic diet is associated with removal of surplus fluid. On the other hand, Byrom [2] failed to detect any changes either in the net water balance or in the amounts lost by any of the excretory routes (urine, skin, &c.) during the twenty-four hours *before* a convulsion. He found, however, that the seizure was followed by a loss of body-weight resulting from the excretion of extracellular body fluid which in turn was succeeded by a retention of water and a corresponding rise of weight. Although he was unable to demonstrate any alteration in the gross amount of water of the body which might lead to an attack, Byrom[2] admits the possibility of an alteration in the normal distribution of water between cells and extracellular spaces.

---

* McCunn Medical Research Scholar. † Muirhead Scholar.

In the hope of obtaining some information on this problem we investigated the water content of the blood obtained from epileptic patients during a fit and compared the findings with those obtained in the quiescent stage. To do this the percentage volume of red cells, serum protein, and whole blood chloride were determined. Normally the ratio of corpuscles to plasma is about 40 to 60. Any change in the degree of hydration of the blood will be reflected by an alteration in this ratio. Changes in the concentration of plasma protein and blood chloride will also indicate abnormality in the water content of the blood. At the same time it was found possible to obtain values for the serum calcium, phosphorus, and phosphatase.

The researches of others on serum calcium are too numerous to quote; a summary of the more important results is given in the monograph by Lennox and Cobb,[3] who conclude that the calcium content of the body fluids in epileptics is normal. Recently a paper has appeared by Spitzer,[4] who states that more than half the number of cases of true epilepsy show deformities of teeth and suggests that there may be interference with thyroid and parathyroid action. It was therefore thought worth while to determine the value of serum calcium and phosphorus and phosphatase, the latter substance being a ferment the amount of which is affected by parathyroid activity, and which itself plays an important part in calcium and phosphorus metabolism

Table showing Blood Analysis in Epileptics

—		No. of cases.	Range.	Mean.	Standard error.	Standard error of diff. of means.
Serum calcium (Mg. %)	F.	31	8·6 –11·7	10·28	0·55	0·16
	Q.	32	8·4 –11·4	9·94	0·22	
Serum phosphorus (Mg. %)	F.	30	2·2 – 4·5	2·996	0·41	0·14
	Q.	30	1·9 – 4·0	2·88	0·36	
Plasma phosphatase (units %)	F.	30	2·3 – 9·0	4·56	1·17	0·40
	Q.	30	2·5 – 8·5	5·16	0·94	
Red blood-cell (per cent. vol.)	F.	24	24·2 –53·3	40·36	4·56	1·68
	Q.	24	31·8 –47·3	38·75	3·20	
Serum protein (g. %)	F.	24	6·74– 9·40	8·28	0·48	0·21
	Q.	24	6·90– 9·46	8·098	0·51	
Blood chlorine (c.cm. N/10 %)	F.	17	64·30–80·10	74·75	2·69	1·85
	Q.	17	64·20–92·80	76·66	4·39	

F. = fit; Q. = quiescent.

The patients, 32 in number, were all adults and true epileptics, who had been resident in Gartloch Hospital for at least six months. Blood was withdrawn in a quiescent stage of at least three days' duration, and only those samples were accepted which proved to have been taken at least forty-eight hours before a convulsion. In the same patients blood was also withdrawn during an attack. The results are detailed in the accompanying Table.

The percentage volume of red cells was determined by centrifugalising oxalated blood (1 drop of 15 per cent. potassium oxalate solution to 5 c.cm. of blood) for half an hour in a graduated tube. For the quiescent stage the mean value was found to be 38·75 and during a seizure 40·36. These were not found to be significantly different. One finding, however, is of interest—viz., the greater range of red cell volume observed during the fits. Lennox and Cobb[3] report normal values for hæmatocrit readings in 100 epileptic patients, but they do not state whether or not the blood was taken during a convulsion. Although their findings were higher than those recorded here, it is probable that difference in method and the presence of anæmia in some of the present series may account for this variation. Clemmesen[5] examined the blood in normal subjects and epileptic patients while on normal diet, and during a period of inanition; he found no change in the percentage volume of blood corpuscles in either group.

In our series neither serum protein nor blood chloride varied significantly as a result of a fit. The mean value obtained for serum protein (8·10 g. per cent.) (estimated refractometrically) tallied with that recorded (8·3 g. per cent.) by Wuth[6] using the same method. These results indicate that if any interchange of water between cells and tissue spaces does occur, it is not reflected in the blood stream. It is possible, however, that the greater range of values obtained for red cell percentage volume during fits is due to a greater instability of water metabolism during the epileptic convulsion.

It will be seen from the Table that the mean values for serum phosphorus do not differ from those of a normal series. An increase during the fit was shown in 19 cases and a decrease in 9. The mean values for phosphatase determined by the method of Jenner and Kay[7] are lower than normal (6·6). Of 30 cases observed during the fit 13 had values below 4·0 which we consider to be the lower limit of the normal range and only 3 above 6·6. In 19 cases there was a decrease during the fit and in 11 an increase. When, however, the mean values of both phosphorus and phosphatase are considered, it is obvious that neither shows a significant difference as a result of the convulsion.

As regards serum calcium the mean values are within normal limits, but the quiescent figure is 0·34 lower than that obtained during the fit. A statistical consideration of these figures shows that it is just possible that the observed difference is significant, but the probability of this being so is not great enough to justify more than a passing mention. Of the individual cases 20 out of the 32 examined showed an increased value for serum calcium during the seizure. These results suggest that there may be some slight disturbance in calcium and phosphorus metabolism but of a secondary nature.

CONCLUSIONS

Investigation of the blood chemistry of epileptic patients at a quiescent period and during a convulsion does not reveal any significant difference in the composition of the blood, except possibly a greater variation in percentage volume of red cells and a slight rise in serum calcium during the fit. We do not consider that the changes are wide enough or sufficiently constant to lend support to the view that the onset of an epileptic seizure is associated with alteration in water metabolism.

We desire to express our thanks to Dr. A. M. Dryden, medical superintendent of Gartloch Hospital, Gartcosh, for the facilities which he afforded us, and to Prof. G. B. Fleming, Dr. S. Graham, and Dr. N. Morris for their helpful advice.

ATYPICAL MUSCLE STRAIN

By P. Bauwens, M.R.C.S. Eng.

MEDICAL OFFICER IN CHARGE, ELECTRO-THERAPEUTIC DEPARTMENT, ST. THOMAS'S HOSPITAL, AND HON. ELECTRO-THERAPEUTIST, THE ROYAL WESTMINSTER OPHTHALMIC HOSPITAL ; AND

James K. McConnel, D.S.O., M.C., Lt.-Col. (Rtd.)

BIOPHYSICAL ASSISTANT AT ST. THOMAS'S HOSPITAL, LONDON

The following are put forward as the arguments on which the essay is founded :—

Argument

1. Pain which may reach great severity often arises from atypical muscle strain.
2. The sites of these strains are often overlooked, because the usual signs of muscle strain are frequently absent, and often the pain is ascribed to coexistent conditions.
3. The cause of atypical muscle strain is unsatisfactory repair of soft structures due in general terms to ill-health, deficient circulation locally, to chronic local fatigue of muscle, and incoördination.
4. These atypical strains can be located with certainty by simple electrical tests.
5. Satisfactory results from treatment demand a reasonably good state of health, so that the appropriate local remedies may take effect. Bad muscular habits which induce local muscular fatigue must be adjusted.

When flaccid, a muscle should be sufficiently extensible not to suffer strain within the normal range of joint movement, so that it is reasonable to suppose that muscle-fibres which happen to be inactive do not suffer strain. But, if a sudden force is applied while a large number of muscle-fibres are contracting, strain is likely to occur. Again, if a sudden force, such as would arise through loss of balance, is applied when a muscle is under a light load, more fibres come into action by reason of the "stretch-reflex" mechanism ; if the force does not yield to this reinforced action by the muscle, strain may take place. In both these circumstances a number of neighbouring fibres are in action and can become damaged, as they are subjected to considerable force. If damage results, a condition of acute strain is found at a point which is recognisable by tenderness over the site of injury, by swelling and by increased pain on voluntary movement. This constitutes the classical muscle strain which is rarely overlooked. Milder forms of the acute condition are seen. They are as a rule easily recognised, although one or more of the signs of acute muscle strain happen to be absent. The inflammation that follows an acute muscle strain should lead to a satisfactory repair, and the scar tissue which is laid down should not impede the subsequent function of the muscle. This is not always so.

HYPERSENSITIVITY TO THE FARADIC CURRENT

In certain cases it has been noticed that a few weeks after a strain portions of a muscle are distinctly hypersensitive to the faradic current, so that the patient experiences a sensation of needle pricks, of a bruise, or of a sharp boring-in pressure, whilst on the surrounding undamaged muscle the identical current gives the usual feeling of quiver. Hypersensitive areas located in this way are frequently found at the same time as the patient is experiencing either referred or diffuse local pain ; in fact, sometimes stimulation of the hypersensitive area gives rise to this pain. After suitable local treatment of the areas in question both the hypersensitivity and the pain disappear. There thus appears to be a definite relationship between atypical muscle strains and pain which is either referred to a distant part or is local, although vague and diffuse. To explain this hypersensitivity to the faradic current is not easy, but possibly scar tissue, formed within the muscle after the accident, is contracting down on nerve filaments in contact with it and rendering them irritable. The symptoms may be conveniently regarded as being the result of matting together of fibres of muscles or fascia and sensory nerve twigs, possibly due to the organisation of an inflammatory exudate.

In many cases there is no history of a strain, but as a result of a hypertonic condition of the muscles in question one finds a local chronic fatigue, as will be described later.

Characteristics of Atypical Muscle Strain

Of the characteristics from a clinical point of view the first four are of special importance.

1. Lack of tenderness to pressure.
2. Delay before the patient experiences pain due to the atypical strain. This delay is sometimes a matter of weeks.
3. Absence of pain on passive movement.
4. Absence of objective physical signs, such as swelling or redness.
5. Diffuseness.

When hypersensitivity to the faradic current is found in muscles, this is frequently diffuse over quite a large area. It is often found along lines of mechanical stress in a series of muscles that are used in some occupation or habit, rather than within definite anatomical boundaries. It is not easy to explain why diffuse damage should occur in the belly of a muscle without localised damage at any one point producing classical signs of acute strain. When light work is being performed, muscle-fibres come into play in rotation in a manner similar to the process found in the capillaries. In a muscle with lowered vitality through chronic fatigue or ill-health, it would seem that, when the local load is suddenly increased, instead of a reinforcement by further muscle-fibres occurring through the "stretch-reflex" mechanism, the individual fibres which happen to be contracting become damaged.

6. Another distinction between the acute and this atypical form of muscle strain is the *absence of pain on active movement*, which is often a characteristic of the latter. This absence of pain does not preclude the existence of strain in a muscle because, when a muscle contracts during a voluntary movement, only a portion of its fibres are brought into use. It therefore seems quite feasible that the absence of this sign of strain is noted, because the strained portion of the muscle was not brought into play during the voluntary test.

We must mention that stretching a muscle affected in the manner under discussion may produce referred or diffuse local pain. Confirmation of this must, as a rule, rest on the elimination of the pain following treatment of the hypersensitive portion of the muscle, as it would of course be hard to show absence of pain from neighbouring

structures involved in the movement. Hypersensitive areas in the abdominal wall sometimes exemplify this. When the strained muscular wall is stretched as a result of flatulence, pain may be severe and may radiate extensively, often down to the scrotum. After treatment, flatulence causes similar stretching of the muscular wall, but without the pain previously experienced.

7. In some cases after these strains have been cleared up an increased range of joint movement has been reported by the patient, and is noticeable to an observer. This seems to indicate that these atypical strains can be responsible for local muscle spasm in their vicinity. This spasm produces local chronic fatigue, which predisposes to further atypical muscle strain. It is thus a feature of these strains that the area affected tends to increase in size with the passage of time.

8. Absence of tenderness to touch and other recognised signs of muscle strain may lead to the pain being ascribed to another factor, especially if some disability such as gross osteo-arthritis of the hip-joint is coexistent. We have seen this occur, where severe pain felt down the inside of the leg to the knee was subsequently shown to be due to atypical strain located in the gluteus medius muscle and in fascia near the great trochanter; similarly, pain felt in the groin and radiating down the inner side of the leg was due to atypical strain in the pectineus and sartorius muscles. It thus seems reasonable to add a final characteristic, namely, elusiveness, realising that it is merely an indication for applying an electrical test rather than an adequate proof of strain. At the examination the presence of these atypical strains arouses an impression that something beyond the evident bodily defects is needed to account fully for the degree and distribution of the pain, discomfort, or weakness of which the patient complains, or which he appears to have. This feature of elusiveness possessed by atypical strains is sometimes responsible for patients being erroneously described as neurotic; the electrical tests, however, throw valuable light on this difficult question.

Causes of Atypical Muscle Strain

Whilst admitting that there are other points of view, it does not seem that any of the cases we have studied during the last seven years require any more complex explanation than is given below. We are grouping the factors affecting the situation under four headings for the sake of clearness, although in practice they usually interact, so that it is hard to settle their relative importance or, sometimes, to pick them out individually. This interaction often presents a difficulty when choosing a line of treatment, and is thus important clinically.

1. *Trauma during ill-health.*—We have already alluded to causes and mentioned that possibly organisation of inflammatory exudate within a muscle contracts down on sensory nerve twigs and renders them irritable. Whatever may be the exact nature of the cause, we can describe it in general terms as an unsatisfactory repair of the soft structures. One group of factors which predispose to a failure in repair comes under the heading of a poor state of health.

2. *Stasis and poor blood-supply.*—Unsatisfactory repair of the soft structures tends to occur in the presence of poor blood-supply and stasis. Thus, exposure to cold, general fatigue, or reduced activity (either due to pain or during immobility owing to the treatment of a fracture) may lead to an acute muscle strain becoming chronic by assuming this atypical condition. The result of a combination of cold, deficient blood-supply, lowered activity of intrinsic muscles, and local engorgement of tissues is sometimes seen in the feet of patients with a poor circulation. Under these conditions minor strains arise and, as they fail to clear up, the patient experiences pain due to irritation of the sensory nerve twigs involved.

3. *Weakness and incoördination.*—Atypical strains are also found in weak and incoördinate muscles on which a heavy load is suddenly thrown. For example, these diffuse strains are seen in the gluteus maximus muscles in the patients who, through bad habit, do not normally use these muscles, but rely too much on the hamstrings. Their buttock muscles thus become anæmic and infiltrated with fatty tissue. When an unusual exertion such as stepping off a bus is made the buttock muscles suffer and, being normally little used, repair does not proceed in a satisfactory manner. Hence a state of atypical strain supervenes.

Athletes who train too rapidly may subsequently suffer from atypical muscle strains.

Strain due to incoördinate action also occurs in muscles which suffer from local chronic fatigue. These *fatigued muscles are prone to injury with inadequate* cause; an awkward movement, as when tying a bootlace or lifting something, is enough to produce strain. Possibly local chronic fatigue upsets normal coördination and synergic action of muscles. When patients with these troubles are watched performing purposive movements with the muscles in question exposed to view or to touch, a staccato action in place of the usual rhythm is seen. As the precipitating cause is so trifling, and as the latent period before pain is felt is sometimes a matter of weeks, the significance of chronic local fatigue is sometimes missed: the trifling nature of the accident suffices to produce an atypical strain, but does not lead to the classical symptoms of an acute strain.

4. *Local chronic fatigue in hypertonic muscles* predisposes to atypical strain in muscle in the following manner. Normal muscle tone implies a state of slight constant tension which is caused by individual muscle fibres contracting in rotation. In order that the integrity of the muscle may be safeguarded, it is essential that the individual fibres be given adequate periods of rest in the relaxed state, and this is provided for by the continuous interchange of active fibres. Increased tone is obtained by a larger proportion of fibres becoming active at one time, and under these circumstances the resting phase for individual fibres becomes reduced. Hence, if this increased tone is prolonged, fatigue products tend to accumulate. This accumulation of fatigue products during sustained static contraction is accentuated by the relatively small volume of blood that traverses the muscle during this form of activity. Possibly this volune exceeds the low blood-supply in a resting unfatigued muscle, but it is totally inadequate for the demands of the muscle, and cannot be compared with the rich supply induced by exercise which involves alternate contraction and relaxation.

If, therefore, muscles are kept for long periods in a hypertonic state, chronic fatigue sets in, and it is not surprising that under these conditions we should often find unsatisfactory repair of the soft structures, which leads to atypical muscle strain. This is observed clinically even in muscles which show an unusual amount of development. It seems also that the chronic fatigue gives rise to mild persistent damage of soft structures, which will suffice to begin the trouble without the occurrence of any recognisable injury. In these cases where pain has supervened, no permanent relief is obtainable until the hypertonic state has been dispensed with. Restoration of the normal muscle balance is thus an essential part of treatment.

Detection by Electrical Tests

Hypersensitive areas associated with atypical muscle strain can be conveniently located by two methods. The first is by means of minimal faradism using the current drawn from the Smart-Bristow coil. This is convenient, because this coil is in constant use and is well understood. As already described, the patient notices differences of sensation when the current is passed through normal muscle and muscle suffering from atypical strain. The peculiar sensation of pain, when the electrode is applied to the area of strain, is never confused by the patient with the normal sensation of faradism. This minimal faradic test uses a low voltage current, and the amount of the current which passes to the muscle under test depends on the electrical resistance of the overlying tissues. If the horny layer is thick, if it is patchy—as when local exposures of ultra-violet rays have been given—if the patient is very fat, or if the muscle in question lies very deep, the results of the test may be hard to evaluate.

The second method is to use a current which reaches the damaged muscle without being affected by variations of resistance of the superficial tissues. This is achieved by fully rectifying an alternating current without any smoothing, and controlling it by regulation of the filament current of the rectifying valve. This current being of an unidirectional pulsating nature has an added advantage of being easily measured by means of an ordinary milliammeter. It may conveniently be called "rectified A.C."

When using this rectified current for testing, it is essential to keep constant the area of contact between the electrode and the patient's skin. Thus, considerable care is needed, when testing over prominent bony points, such as the epicondyle of humerus. If this area of contact is kept constant, there is no possible risk of using an excessive current flow or density, as with a suitable arrangement of resistances control of the patient's current is most satisfactory. The method has advantages over the faradic current.

Treatment

A poor state of health was given as a cause for failure in the initial repair of soft structures and the consequent production of atypical muscle strains. It is of equal importance when we are aiming at bringing about an adequate repair by means of local remedies. Improvement of general health is beyond the scope of this article, so we shall not deal with this aspect of the subject which, with certain patients, is of the utmost importance. It must be mentioned that many patients who acquired atypical muscle strains when in a poor state of health are found to be perfectly fit when they come for treatment; this shows that a return to normal health alone may be insufficient to improve the muscular condition.

LOCAL REMEDIES

A satisfactory choice of local remedies often gives results in a single treatment, but to achieve this localisation of the site of atypical strain is essential, so that the beneficial effect of the treatment is not wasted on other areas. It is of relatively little value to treat an area of referred pain as compared with treating the site of the atypical strain, hence the great importance of the electrical tests in all but the simplest cases.

Two remedies for atypical strain which are generally efficacious are local doses of ultra-violet rays and histamine ionisation. The effects of these are somewhat similar because local doses of ultra-violet cause a liberation of small quantities of vasodilatory substances over a long period, producing the characteristic "triple response."

Broadly speaking, the former of these two is able to cover at one sitting a larger area than the latter, and give a longer effect, but may be correspondingly less potent. Where the skin is thick, as on the sole of the foot, or where it is deeply pigmented from exposure to the sun or to ultra-violet rays, histamine ionisation is more useful. On the other hand, histamine ionisation must be used with great care, and must never be given when there is gross heart disease or low blood pressure; occasionally the effects on respiration and on peristalsis are contraindications, with allergic patients. Often the choice between these two depends on expediency; it is unwise to make a local pigmentation by ultra-violet on the shoulder of a lady who wears evening dress, and it is equally undesirable to give a histamine headache to a business man who is about to put through an important deal.

Massage, radiant heat, infra-red rays or diathermy (either short or long wave) often do not succeed, and may even exacerbate the pain. They may, however, prove useful adjuncts to local doses of ultra-violet or to histamine ionisation.

RESTORATION OF MUSCLE BALANCE AND NORMAL RELAXATION

This must be dealt with briefly, so as to keep in line with the foregoing. The adjustment of faulty muscular habits which produce chronic fatigue in hypertonic muscles is, as a rule, simple, even with the elderly and decrepit, but not so by the usual method of repeating the desired movement or posture as an exercise, because this deals with one side of the problem only.

These bad habits occur unnoticed by the patient, as they belong to the background of his daily activities being almost part of himself. Thus, sensations connected with them must be pointed out to him, and made to stand out like highlights against this background, whenever they recur; for example, pressure of the collar against the neck can be used to remind the patient of a poking forward of his chin. The bad habits are often linked up with emotions such as the fear of falling or of pain on movement, sometimes being the patient's response to instability of his feet or ankles. Unless newly forming habits are practised under conditions which do not arouse these unconscious fears, much time will be wasted.

Purposive movements, such as rising from a chair, must be encouraged in a painless manner. Conditions which encourage the good habit must be studied; when walking upstairs, the patient will probably avoid a retracted neck position which may have been associated with a spasm of the lumbar muscles, if he looks at the step on which he is going to place his foot. It is essential to train sensation, so that the patient can check the results of his efforts; should he experience any feeling of effort in the fatigued muscles, when doing a movement, it cannot have been done correctly. The knowledge of success each time he tries and the relief to his previously hypertonic muscles form a talisman against relapse for the patient who knows how to help himself with understanding.

THE ELECTRICAL TESTS

A test for atypical muscle strain should be applied after each series of two or three treatments, when dealing with difficult cases, as this regulates the programme of treatment outlined before treatment began. This is important when coexistent conditions are present and may themselves require attention, or when several areas of atypical strain appear to refer pain to the same distal area. It is also most useful when an atypical strain giving a diffuse local pain exists in a portion of the body to which pain is referred by other distant strains. As an example of this, one may mention how some patients, on the one hand, feel pain referred from the lower back or the buttock muscles to the foot and below the knee, and, on the other hand, have atypical muscle strain near the external malleolus, which gives a diffuse local pain in the same area. The tests, of course, locate strain in the fascia as well as in a muscle belly.

Conclusion

We wish to emphasise that atypical strains are liable to be overlooked; that the pain they produce is likely to be ascribed to other causes; and that the electrical tests which elicit these strains are therefore clinically important.

We wish to express our gratitude to Mr. A. T. Fripp for his valuable suggestions as regards the production of this article.

THE TONSIL AND ADENOID OPERATION

REASONS FOR REVERSAL OF THE USUAL ORDER OF REMOVAL OF THE TONSILS BEFORE THE ADENOIDS

BY D. F. A. NEILSON, F.R.C.S. Eng.
ASSISTANT SURGEON, EAR, NOSE, AND THROAT DEPARTMENT, ST. THOMAS'S HOSPITAL, LONDON

THE operation for removal of the tonsils and adenoids in children is such a common one and is in practice performed by such a variety of surgeons that it is surprising that there is almost complete unanimity in dealing with the tonsils prior to the adenoids. A few text-books have mentioned the fact that the usual order of the operation might be reversed, but it is probable that the general belief in the safety of a short and light anæsthesia has made it essential that the nasopharyngeal part of the operation should be done last; because, whereas every step of the tonsil removal is taken under full visual control, the nasopharynx, on the other hand, can only be examined digitally, and during the adenoidectomy there is next to no risk of serious instrumental injury to some vital tissue—an accident which is always at the back of the surgeon's mind as a possible if highly improbable complication during the removal of the tonsils.

The advent of the use of the Davis gag, the elimination of the use of the blunt or sharp guillotine, and the safety of a longer and deeper anæsthesia, has made possible a much more deliberate technique, and therefore other methods may be worthy of consideration.

When the patient is in the extended head position and with the pharyngeal reflex abolished by the anæsthetic, it is possible by using a Davis gag (or any form of dental gag with displacement of the tongue) to obtain a complete view of the field of operation for the removal of the tonsils, and with a little practice the operation can be carried out quickly and with only slight hæmorrhage. It is therefore very unusual to see a child who has been operated on by this method with a so-called "tonsil remnant" showing later. Although the actual tonsillectomy has been made so much easier by the improved view of the operation field, the only additional help with regard to the adenoidectomy is that the removal may be more deliberate owing to the continued administration of the anæsthetic.

It is in my experience fairly common to meet with a child in whom there has been a partial and unsatisfactory removal of the adenoids, but uncommon to see one in whom there has been an incomplete tonsil removal. This is because, as has been stated above, the tonsillectomy is no longer a "trick" operation, but in performing adenoidectomy the surgeon is still compelled to work in a cavity which it is impossible to inspect and by inspection make sure that his operation has been completed.

For several years now I have invariably practised the removal of the adenoids as the first stage in the tonsil and adenoid operation. The exact method of removal of the adenoids is not here under consideration, but it is not so easily carried out with the Davis gag as with a simple incisor gag, owing to the fact that the tongue blade of the Davis gag puts tension on the faucial pillars and this makes instrumentation of the nasopharynx more difficult.

The adenoid operation is started under exactly the same depth of anæsthesia as is required for the tonsillectomy and with the head in the same extended position. As soon as the removal of the adenoids has been completed and the surgeon has satisfied himself by a careful digital examination of the nasopharynx that the adenoid tissue has been completely removed, the nasopharynx is firmly packed with a gauze plug. Hæmorrhage from the nasopharynx is thus at once completely checked. The tonsil operation is then performed in the usual way, and if an ordinary form of dental gag has been used for the operation up to this point it can be safely removed and a Davis gag substituted.

It may here be objected that the fact that the nasopharynx is completely filled with a plug will add to the difficulty of the tonsil operation, since the blood cannot escape from bleeding tonsillar vessels into the nasopharyngeal cavity and will tend to fill the mouth more rapidly. This is to a certain extent true, but it should be possible to carry out the tonsil operation with so little hæmorrhage that this can be easily dealt with as the blood collects, without in any way endangering the airway; and if it is thought necessary a suction apparatus can be kept ready to remove any excess of blood. If more than one nasopharyngeal plug is used it is absolutely essential that the number of plugs or sponges should be counted, so that it is made certain that they are removed at the end of the tonsillectomy operation; and it is probably safer only to use plugs that have a thread or thin tape attached to them.

ADVANTAGES

The following advantages are obtained by operating on the adenoids as the first stage:—

1. The adenoid operation is carried out with the faucial pillars still intact and supported by the tonsils and there is therefore no danger of tearing or damaging them when passing an instrument or an examining finger into the nasopharynx. This is an accident which may occur if the tonsils have been removed first, particularly in small children and when the Davis gag is used, and although it may be considered trivial it will result in unnecessary scarring.

I consider that it is absolutely essential to digitally examine and as far as possible inspect the nasopharynx immediately after the adenoidectomy.

2. As soon as the adenoid operation is completed the nasopharyngeal plug arrests the hæmorrhage and there is less actual loss of blood than if the bleeding is allowed to stop by the ordinary process of clotting.

3. It is a great advantage that at the end of the adenoid and tonsil operation, after the removal of the nasopharyngeal plug, the child can be at once removed to bed with less risk of a blood clot forming in the deep pharynx; and there will be less soiling of bed linen due to blood trickling away from the nose.

4. I certainly think that the frequently applied method of removing the adenoids while the patient is "coming round" from the anæsthetic cannot be too strongly deprecated. Under these conditions the palate muscles contract and the adenoid operation is

rendered much more difficult and at the same time, owing to the liability of the patient to stop breathing by contraction of the laryngeal muscles followed by a sudden violent inspiration, there is more risk of blood and infected secretion being sucked into the lower air-passages.

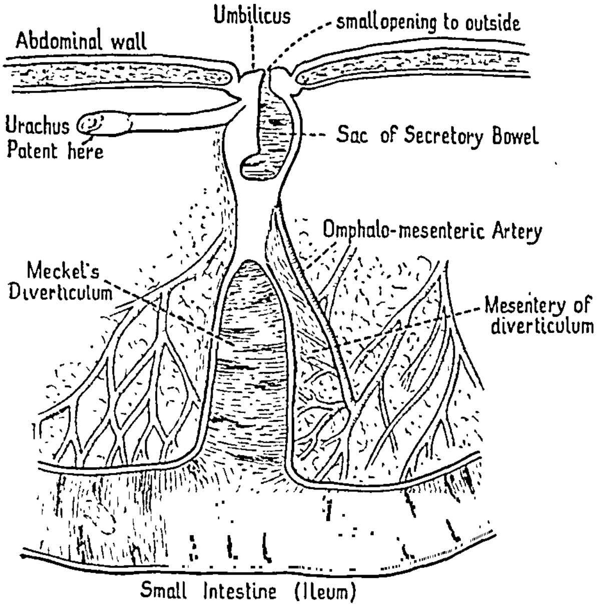
Clinical and Laboratory Notes

AN UNUSUAL CASE OF MECKEL'S DIVERTICULUM

By John A. Mackenzie, Ch.M. Aberd.
SURGEON TO THE VICTORIA HOSPITAL, BURNLEY

Meckel's diverticulum, according to Keith, is the persistence of the intra-abdominal part of the vitello-intestinal duct; and although it normally disappears, vestiges may remain and give rise to symptoms varying from slight discomfort to intestinal obstruction. The following case is an unusually complete example of the various characteristics of the condition.

A. B., aged 10 years, came to my out-patient department complaining of a dermatitic condition of the skin round the umbilicus. His statement was that this started three weeks ago, and was due to a "kick in the stomach" when swimming in the baths with some other boys. His mother stated that his cord was very thick at birth and difficult to heal, requiring cauterisation. For the first six years of his life he had complained at times of vague abdominal pains in the region of his umbilicus, but he never had any nausea or vomiting, and there was no difficulty in feeding him in infancy. From six to ten years of age he had had no trouble whatever until this eczematous condition of the skin started round the umbilicus.



On examination the umbilicus was found to be retracted, and a dirty brownish-yellow discharge exuded from it, causing the eczematous condition of the skin. No symptoms of interference with the bowels were present, and nothing could be felt on palpation. I put on a broad Elastoplast bandage over the umbilicus and told the boy to report in two days. When I took the elastoplast off about half an ounce of dirty yellowish fluid came from the umbilicus, homogeneous in character, with no flakes or granules in it. I repeated this, and a larger quantity came out the second time; accordingly I decided to admit him to the ward and explore, expecting to find a patent urachus. On August 21st, 1934, I explored by an elliptical incision so as to remove the umbilicus and whatever was attached to it, and found the following condition. Running from the ileum up to the umbilicus was a well-marked Meckel's diverticulum. (See Figure.) This arose almost close to the mesenteric border of the ileum, and its lumen was the same as that of the ileum. It was 4¾ inches long and attached to the umbilicus. For the first 3 inches from the ileum the lumen was patent; then about ½ inch fibrous tissue supervened; this, again, opened out into a cavity 1¼ inches in diameter, which communicated by a small opening into the umbilicus. On splitting this cystic end open I found it lined with mucous membrane; to all outward appearance it looked like a piece of duodenum or jejunum, with rugæ secreting fluid which was being discharged through the small sinus into the umbilicus. This diverticulum had a mesentery of its own, attached to the mesentery of the bowel, and along the free edge of this mesentery ran an omphalo-mesenteric artery the size of a fairly large quill. This was attached to the umbilicus at one end, and ran out into the mesentery of the ileum. Also attached to the umbilicus and running down the right side was a large urachus, patent up to within 2 inches of the umbilicus.

The usual operation was done with a Kocher's clamp, and the diverticulum was treated as an appendix and sunk by a continuous Lembert suture. The abdomen was closed and the boy made an uninterrupted recovery.

The chief points of note in this case are: (1) there were no signs or symptoms of obstruction or interference with the bowel at any time; (2) the part of the bowel next the umbilicus, and shut off from the intestinal part of the diverticulum, was actively secreting fluid which caused the irritative dermatitis; (3) this seemed to have been stirred to life by the kick in the abdomen; (4) the Meckel's diverticulum, with its mesentery complete, and the omphalo-mesenteric artery and the urachus were all conspicuous and present together.

FURTHER NOTES ON THE LABORATORY USE OF SCREW-CAPPED BOTTLES

By J. E. McCartney, M.D., D.Sc. Edin.
DIRECTOR OF RESEARCH AND PATHOLOGICAL SERVICES, LONDON COUNTY COUNCIL; AND
T. H. Ayling
SENIOR TECHNICIAN, SOUTHERN GROUP LABORATORY
(*From the Southern Group Laboratory, Park Hospital, London, S.E. 13*)

Details of the use of screw-capped bottles in the preparation and storage of culture media, for blood culture bottles, and as a substitute for test-tubes have previously been described by one of us.[1,2] These methods have proved very satisfactory; the following further uses will be of assistance, particularly for routine use in pathological laboratories.

"*BIOCHEMICAL BOTTLES*"

For the various routine biochemical methods, several kinds of anticoagulants or preservatives are mixed with the blood according to the examination required—e.g., potassium oxalate, sodium fluoride, and sodium citrate. In order to ensure that the correct anticoagulant is used, and in the proper amount, small screw-capped bottles, with painted tops and covered with a Viskap, are used. The bottles employed are the 1 oz. screw-capped vials H. 53 previously described [2] and fitted with a perforated cap and rubber washer, as used for the blood culture bottles.[1] The same aluminium cap also fits the 4 oz. and 6 oz. medical flats. The blood is added to the bottle by puncturing the rubber washer like a vaccine bottle.

Method.—The caps discarded from the bottles used for media are utilised. They are placed in weak lysol which not only sterilises them from any culture organisms, but softens the white paint on them so that it is easily rubbed off. The liners are removed and the caps washed and dried. A hole ¼ in. in diameter is punched out of the cap and a red rubber washer 2 mm. thick is fitted. To the sterile H. 53 bottles the correct amount of anticoagulant is added, a perforated cap is screwed on, and the top painted with cellulose paint according to the following scheme, which has been standardised :—

Anticoagulant and amount.	Colour of top.	Test.
Sod. fluoride 10 parts Thymol .. 1 part } 0·1 g.	Red.	Blood-sugar.
Pot. oxalate 0·25 c.cm. (4 drops) 20 per cent. (evaporated)	Blue.	Blood-urea.
Sod. citrate, 20 per cent., 4 drops.	Purple.	,,
Mixed fluoride and oxalate, 0·5 c.cm.* (evaporated).	Yellow.	Blood-sugar. Blood-urea.† Non-protein nitrogen.
None—plain empty bottle ..	White.	Where ordinary serum required—e.g., Widal, Wassermann. blood calcium, &c.
Glass beads, 3 mm. diameter	White.	For defibrinated blood.

* Pot. oxalate .. .. .. 3 g.
Sod. fluoride .. .. .. 4 g.
Distilled water .. .. 100 c.cm.

† Fluoride prevents the use of the urease method.

With the potassium oxalate and mixed fluoride-oxalate the solution is placed in the bottle, which is rotated so that the fluid moistens most of the interior, and then placed in the hot-air oven (coolest shelf) to dry. When the bottles are removed and cooled, the cap is screwed on.

With the plain bottle and bottle with beads, new caps are used because they are already painted white when received. When the cellulose paint is dry (30 minutes) a transparent viskap (No. 2, cut 1½ in.) is placed over the cap and allowed to dry. In doing so, it shrinks and moulds itself to the shape of the top of the bottle.

Use.—A red, blue or purple-capped bottle is used according to the test required. The viskap should not be removed. The top of the viskap is wiped with a little methylated spirit which is allowed to dry. Blood is withdrawn from a vein into a syringe in the usual manner. The needle is then plunged through the viskap and washer, and the blood squirted into the bottle. The needle is withdrawn, and the bottle gently rotated until the anticoagulant is dissolved. The top is wiped with a little spirit before being sent to the laboratory.

The advantages of this method are : the bottles can always be kept in readiness ; being sealed there is nothing to deteriorate ; neither can fluid (e.g., citrate solution) evaporate ; the bottles are easily identified by the nursing staff ; the intact viskap shows the pathologist that the bottles have not been opened, and that the contained anticoagulant has not been emptied out or spilt. From the colour of the cap the pathologist can tell at once if the correct bottle has been used for the test required ; thus, if he received a blue cap (oxalate) and the request form asks for blood calcium he will not waste his time proceeding with the test. The bottle with beads is useful for defibrinated blood in the malaria treatment of general paralysis.

Many thousands of these bottles have been distributed throughout the Council's laboratories and have proved extremely useful.

FOR ANAEROBIC CULTURES

The bottles (substitutes for test-tubes) containing culture media are fitted with perforated caps and rubber washers as above when the medium is sterilised, and a supply of such bottles should always be available. Being "canned" the contents will not evaporate or deteriorate, but will keep indefinitely. Alternatively a supply of sterile perforated caps may be kept and used as required.

After the medium has been inoculated the perforated cap is screwed on tightly. A hypodermic needle (No. 22 SWG) is fitted to a piece of pressure tubing, the other end of which is connected to a Geryck pump. The needle is plunged through the rubber washer and the pump started. After a few strokes the air will be entirely exhausted and the needle is withdrawn. The puncture in the rubber is self-sealing, and the vacuum will be maintained for many months. Tests taken when the tube was opened under water three months after exhaustion showed that an almost perfect vacuum had been maintained, there being only a tiny bubble of gas in the bottle. If it is desired to introduce any gas such as CO_2, or a mixture of gas (e.g., CO_2 and air) for *Brucella abortus* cultures, it is only necessary to connect a hypodermic needle to the supply, pierce the rubber washer, and allow the gas to enter. Usually we do not admit any gas after exhaustion, and we have found this method extremely simple and reliable. It is useful for the recognition of *B. welchii* in milk cultures. Any gas evolved is "absorbed" by the vacuum, and no bursting of containers or spilling of liquid will occur. The cultures in the small bottles on solid culture media can frequently be used for isolating anaerobes without recourse to Petri dishes. Where a number of bottles are being exhausted it is advisable to keep the Geryck pump working all the time and have a pinch-cock on the pressure tubing to the needle. The washer is pierced, the pinch-cock opened and exhaustion proceeds, the pinch-cock is closed and the needle withdrawn. This method gives a satisfactory vacuum in a few seconds.

A CASE OF UTERUS DIDELPHYS

ASSOCIATED WITH HÆMATOCOLPOS OF THE RIGHT VAGINA AND SIMULATING APPENDICITIS

BY L. MARTINDALE, C.B.E., M.D. Lond., F.C.O.G.
HON. SENIOR SURGEON, NEW SUSSEX HOSPITAL, BRIGHTON, AND HON. SURGEON, MARIE CURIE HOSPITAL, LONDON

THE following case seems worthy of record not only in view of the difficulty in diagnosing it but also because uterus duplex separatis is rarely seen in living women, being normally associated with other malformations of the pelvis that are incompatible with life.

The patient, a girl of 12½ years, complained of severe dysmenorrhœa, tenderness of the abdomen, and vomiting. On examination she was found to have a temperature of 100° F. and a pulse of 100. There was definite abdominal tenderness, more marked on the right side ; she had already had three monthly periods, somewhat profuse, and the present one had started the day before and was excessive. Rectal examination disclosed a low pelvic tumour about the size of a grapefruit.

As the diagnosis was not clear an examination under an anæsthetic was performed on the following day. The patient was put in the lithotomy position ; hæmatocolpos was found on the right side, the septum bulging towards the left. The left vagina was carefully dilated and a separate cervix found, which was functioning normally. The septum was therefore dissected away, followed by the flow of from 6 to 8 ounces of dark black blood. A few catgut stitches were inserted through the fold of mucous membrane between the two cervices to stop the hæmorrhage, and the fluid was allowed to drain slowly away. The patient made an uninterrupted recovery.

Thirteen years after this operation I had occasion to examine the patient again under an anæsthetic, partly because she was still suffering from occasional dysmenorrhœa and some menorrhagia, and partly because there was a question of a possible marriage. On this occasion I found a wide vagina, two cervices, and the remains of the base of the vaginal septum; the right cervix was caught up to the right wall, the left being more central, and the uterus felt broader than usual. The left cervical canal admitted the uterine sound with ease, the length of the cavity being 6 cm. I dilated the canal up to No. 9 Hegar, and took some curettings for examination. The right cervix only admitted the sound for 4 cm., and no curettings were obtainable. The pathological report on the curettings from the left side was that "the uterine endometrium showed some areas of interstitial hæmorrhage, possibly due to the curettage."

The difficulty in diagnosis is of some interest. The fact that there had been three normal periods made one hesitate to diagnose hæmatocolpos; the pyrexia and definite right abdominal tenderness and pain and the vomiting suggested appendicitis. A blood count was not done, but, even had it been, a leucocytosis would have been compatible with both a hæmatocolpos and an appendicitis. The patient is a normal girl in every other way.

REVIEWS AND NOTICES OF BOOKS

Surgical Diseases of the Chest

By Evarts Ambrose Graham, A.B., M.D., F.A.C.S., Professor of Surgery, Washington University School of Medicine; Jacob Jesse Singer, M.D., F.A.C.P., Associate Professor of Clinical Medicine to the School; and Harry C. Ballon, M.D., C.M., F.A.C.S., formerly Assistant Professor of Surgery to the School. London: Henry Kimpton. 1935. Pp. 1070. 65*s*.

The surgery of the chest is advancing so rapidly that, as the authors say, it is inevitable that some of the opinions expressed in any comprehensive work on the subject should already be out of date at the time of its publication. This work is unusually up to date in most places and only a specialist would detect the others. The material is treated authoritatively and each chapter is followed by a full and classified bibliography. The subjects described include everything that has ever been surgically treated in the chest from the cardiac valves and the œsophagus to the bones forming the thoracic cage. Certain chapters are outstanding. The one on bronchiectasis, for example, begins with an informative discussion of modern views on the ætiology of this condition and ends with a well-balanced review of the benefits that may be expected from various operative measures and the risks attendant on each. To the section of the book which deals with pulmonary tuberculosis Dr. R. C. Matson contributes a chapter on adhesion cutting in which he shows a preference for his own method of diathermy as opposed to the original Jacobæus electrocautery technique. An excellent chapter on oleothorax, its uses and limitations, was written by the late Dr. R. W. Matson, who unfortunately did not live to see the publication of the book. The chapter on the surgical treatment of pulmonary tuberculosis contains a full summary of the indications and contra-indications of thoracoplasty; the two-stage operation appears to be the one most commonly performed but reference is made to the recent tendency to make use of more than two stages. Phrenicectomy, in the authors' opinion, is often performed unnecessarily; although a most useful operation in cases in which paralysis of the diaphragm will be followed by limitation of movement, little or no benefit can be expected when the lung is already fibrotic and the diaphragm fixed. Phrenicectomy should not therefore be considered a necessary preliminary to thoracoplasty. The book concludes with a chapter on the chest service at the Barnes Hospital. St. Louis. The building is designed to provide small well-ventilated wards, each communicating with a balcony and placed conveniently near the operating theatre and X ray department. The facilities for treatment provided thus combine the advantages of a modern surgical hospital with those of a sanatorium.

For the advanced student this will be a valuable book of reference as it contains multifarious information, clearly arranged, which could not otherwise be obtained without laborious search amongst original articles in many languages. Illustrations, largely skiagrams, are plentiful and clearly reproduced.

A Text-book of Biochemistry

Edited by Benjamin Harrow, Ph.D., Associate Professor of Chemistry, New York City College; and Carl P. Sherwin, M.D., Sc.D., Dr.P.H., LL.D., Member of the Staff of St. Vincent's Hospital and French Hospital, New York. London: W. B. Saunders Company. 1935. Pp. 797. 25*s*.

Not very many years ago a student wishing for a text-book on biochemistry had great difficulty in finding one in the English language. To-day he is faced with a choice ranging from small elementary books to large and comprehensive volumes. Happily most of these books are good, though they differ widely in the mode of presentation of the subject, according to whether the author is mainly interested in biochemistry from the purely chemical point of view, or whether he approaches it from a physiological, physical, or pathological aspect. Prof. Harrow and Dr. Sherwin have attempted to avoid this restricted outlook by securing the collaboration of over 30 contributors, including several British workers. The book covers the field of biochemistry. On the whole the sections dealing with the purely chemical side of the subject are the best, and of these the chapter on carbohydrates deserves special mention in that it will bring the reader's knowledge on this complex subject right up to date. The section on the sterols, bile acids, and related compounds is rather disappointing, especially in view of the great advances that have been made recently. The author would have been well advised to go into more detail regarding the chemical evidence for the Rosenheim-King formula for cholesterol, since it is upon this groundwork that the whole of our present knowledge, not only of the bile acids and cholesterol, but also of the sex hormones and of certain vitamins depends. A very valuable chapter is that on the vitamins. In only 40 pages the author has succeeded in giving one of the clearest accounts that is to be found in the literature to-day of the present position. The historical introduction is really excellent; it enables the reader to follow the steps that have led to the establishment of the existence of vitamins and the various methods of separation, and finally the determination of their constitution.

An interesting account is given of immunochemistry, giving prominence to the work of Landsteiner and his fellows. The author of the section on oxidations and reductions has tackled the subject in a fundamental manner and it is possible to see the foundations upon which the modern mathematical conception of oxidation-reduction indicators rests. The account of the hormones has been condensed unduly. Only 20 pages are devoted to this important branch of biochemistry and the historical introduction is definitely misleading. Thus the history of the internal secretory properties of the thyroid contains no mention of the names of Gull, Ord, Horsley, or Murray; it is surely a mistake to repeat in modern text-books the fallacious experiments of Brown-Séquard, and in any case, it is unfair to state that he "founded the science of organo-therapy."

The work as a whole is very good indeed, being both accurate and clear. The references are well selected and we commend the book to anyone requiring either a readable text-book or a not too compendious work of reference.

Diseases of the Heart

Third edition. By John Cowan, B.A., M.D., D.Sc., F.R.F.P.S., sometime Professor of Medicine, Anderson College of Medicine; Consulting Physician, Royal Infirmary, Glasgow; and W. T. Ritchie, O.B.E., M.D., F.R.C.P.E., F.R.S.E., Professor of Medicine and Clinical Medicine, Edinburgh University; Physician to the Royal Infirmary and Director of the Medical Unit of the Municipal Hospitals, Edinburgh. With a chapter on the Ocular Manifestations of Arterial Disease by Arthur J. Ballantyne, M.D., F.R.F.P.S., Lecturer on Ophthalmology, University of Glasgow. London: Edward Arnold and Co. 1935. Pp. 631. 30*s*.

In this new edition the text has been almost entirely rewritten, and much new matter has been included without an appreciable increase in the size of the book or alteration of its character. It is essentially an exposition of the authors' own experience and teaching in cardiology, presented in attractive and readable form.

The chapters dealing with disturbances of rhythm form one of the best sections of the book. The subject is treated comprehensively, yet essentially from the clinical aspect, and all unnecessary technicalities have been avoided. Many illustrative graphic records are included, the attached legends being clear and self-explanatory. In the nomenclature of electrocardiograms of bundle-branch block the authors have not adopted the newest terminology, but they have wisely avoided confusion by abandoning altogether the designations "right" and "left."

No particular plan has been followed in the arrangement of the subject matter and the sequence of the chapters is somewhat haphazard. Rheumatic, syphilitic, and congenital heart disease are separately considered, but arterio-sclerotic heart disease is discussed under various headings, little attention is paid to the heart in hypertension, while the thyrotoxic heart is scarcely described.

The section entitled Diseases of the Arteries is open to criticism. Arterio-sclerosis is defined as a diffuse affection of the arterial tree caused by high blood pressure, and the term arterio-sclerosis is frequently used in the text when hypertension is under discussion. This is likely to prove both confusing and irritating to those accustomed to modern terminology. The statement (p. 559) that digitalis is usually injurious in cases of arterio-sclerosis with hear failure will probably astonish many readers. In the chapter on treatment, more information might, with advantage, have been given about the use of mercurial diuretics such as Salyrgan, which represent the greatest advance in the therapy of heart failure since digitalis was introduced.

Having made some minor criticisms, we must pay tribute to the book as a whole. For a volume of moderate size, it contains an extraordinary amount of information. Statistics based on analysis of the authors' own cases are to be found in all sections of the book, and should prove an invaluable source of reference. The illustrations deserve especial praise; they are almost all original, are beautifully reproduced, and add greatly to the interest of the book. Compared with the last edition, the paper has been improved and, instead of references inserted as footnotes, a serviceable bibliography is appended to the text.

Dictionary of Applied Chemistry

Supplement, Vol. II., N–Z. By Jocelyn Field Thorpe, C.B.E., D.Sc., F.R.S., F.I.C., Professor of Organic Chemistry and Director of Organic Laboratories, Imperial College of Science and Technology; and M. A. Whiteley, O.B.E., D.Sc., F.I.C., formerly Assistant Professor of Organic Chemistry to the College. London: Longmans, Green and Co., Ltd. 1935. Pp. 727. 60*s*.

In compiling the three supplementary volumes—the first of which, covering A to M, was noticed in our issue of March 23rd of this year—the editors have assumed that the inquirer has access to the main work, which appeared ten years ago. Some of the articles in the supplementary volumes deal separately with work done during the last decade; others, and these are the most useful, are really monographs on the present state of chemical knowledge in the particular subject with which they deal. The articles on petroleum, photography, radiology, and spectroscopy, and the classified description of the more recent synthetic medical products are of especial interest, but all through the volume are short notes on things that touch medicine closely, such as protein degradation products, thallium, toad venom, vitamins, which the investigator or research worker will overlook at his peril. The publication of the third volume, which will provide a glossary and a comprehensive index to the supplementary volumes, will restore the full value of Thorpe's Dictionary as an up-to-date guide to applied chemistry.

Some Thoughts of a Doctor

Revised edition. By F. Parkes Weber, M.A., M.D., F.R.C.P., F.S.A. With a Preface by Sir W. Langdon Brown, M.A., M.D., F.R.C.P. London: H. K. Lewis and Co. Ltd. 1935. Pp. 184. 6*s*.

Within the compass of 184 pages Dr. Parkes Weber has written 31 essays and papers on various subjects which he has thought about from time to time. He has something to say on eugenics, on free-will (which he regards as a precious endowment found only in small quantity and in few persons), on the gambling spirit and on nightmares, to pick out only four of the things which have interested him. Throughout he writes modestly and often with humour. The result is a provocative and stimulating book. The contemplative reader, whether agreeing or not with Dr. Weber's views, will admire his scholarship, balance, and essential kindliness of outlook.

Konstitution und Tuberkulose im Kindesalter

By Dr. KURT KLARE, Ärztlicher Direktor der Prinzregent-Leutpold-Kinderheilstatte-Scheidegg. Leipzig: Georg Thieme. 1935. Pp. 42. M.4.

THIS question of seed and soil in tuberculosis is, as the author remarks, of long standing, running as a thread through the whole history of the subject. To the old masters of medicine the habitus phthisicus was the all-important factor. Then came the discovery of the tubercle bacillus and opinion swung to the other side. Now the time has come for assessment and correlation of the two points of view. Dr. Klare interprets the word constitution broadly, so as to include not only man's habitus and his physiological functions, but also his reactions to life and his psyche. Various constitutional factors as they affect tuberculosis in childhood are discussed in turn: the endocrine glands, the effects of puberty, the resistance of the lymphatic system, and so on. Two well-known types of tuberculous child, the hectic-looking, bright-eyed, alert type, and the soft, flabby, dull one are described. These discussions occupy the first 18 pages—i.e., rather less than half of the monograph. The remainder is devoted to a description of cases illustrating various types, with photographs of the children, radiograms, blood counts, and case-histories. The subject is an attractive one, and Dr. Klare leaves the reader with a desire to explore it further.

A Text-book of Histology

Sixth edition. By HARVEY ERNEST JORDAN, A.M., Ph.D., Professor of Histology and Embryology, University of Virginia. London and New York: D. Appleton-Century Company, Inc. 1934. Pp. 738. 30s.

THE chief alterations which have been made in this text-book are in its external appearances. The paper and binding are considerably heavier than in the former editions, and the whole book is enlarged as well as increased in price. A few revisions have been made in the text, the most extensive of which are in the sections dealing with the blood and reticulo-endothelial system. Some new illustrations have been added, but otherwise the general plan of the former editions has been maintained.

Human Physiology

Second edition. By F. R. WINTON, M.D., Reader in Physiology, University of Cambridge; and L. E. BAYLISS, Ph.D., Lecturer in Biophysics, University of Edinburgh. London: J. and A. Churchill Ltd. 1935. Pp. 627. 15s.

THERE are few satisfactory text-books of physiology of this convenient size, because it is difficult to dissociate brevity from a popular type of treatment on the one hand, and a mere cataloguing of facts on the other. In this work the explanations are, for the most part, clear and logical, and the diagrams have been selected from a wide field of original papers; very few of them are of the schematic type, and many convey additional information to the discerning reader. In fact, perhaps the most striking feature of this book is the care with which the illustrations have been chosen and the way in which they amplify the text. The student is presented with a reasonably short account of each subject, but he is brought into contact with the actual experiments which have been made, and does *not* feel that his intelligence has been under-estimated. This edition is a great improvement on its predecessor, much new work having been introduced and some mistakes and inconsistencies in the text eliminated. The authors have drawn freely on the experience of experts in different branches of the subject, and several of the sections have actually been written by them. The book is well up to date, containing the first "text-book accounts" of several recent researches; all sections show evidence of revision; and a useful guide to the literature is supplied at the end.

The book can confidently be recommended to students with no more reservation than that they may have to do a certain amount of additional reading.

Die Behandlung der Knochenbrüche durch den praktischen Arzt

Second edition. By Geh. Hofrat Prof. Dr. FRITZ LANGE. Munich: J. F. Lehmann. 1934. Pp. 142. M.4.20.

THIS small volume has been written with the object of assisting the doctor who has to treat fractures in general practice, without the advantages of specially designed apparatus and opportunities for applying the more modern methods of traction and splinting. Dr. Lange has been impressed with the unsuitability of most of the methods taught to the student when he comes to work in the patient's home, at a distance from special clinics. He considers that the plaster-of-Paris technique is of much more value to the ordinary doctor than are methods of skeletal traction, and describes in detail his special technique and its application to all the ordinary fractures. He applies the plaster, not as does Böhler, directly to the unshaven skin, but over a varying amount of padding. All the important bony points are protected by pads of felt or some other material. Ladders, chairs, and cupboards are most *ingeniously* called into service in slinging limbs during the application of the plaster splint; and temporary extension is obtained by the use of buckets of water, the weight of which can, of course, be easily regulated.

As this book is likely to be widely read, it is worth correcting a misstatement contained in it. Referring to the mortality from fracture of the femur in the late war, and the effect on this mortality of methods of transportation, Dr. Lange states that the mortality in the German army from these injuries was 51·5 per cent. This figure, he says, though serious enough, might have been worse, as the English and French mortality, at the beginning, amounted to 80–90 per cent. The entrance of the Americans into the war, with their better orthopædic technique and their introduction of the use of the Thomas's splint, had, according to Dr. Lange, the effect of reducing this mortality to 5 to 10 per cent. The facts are that Sir Robert Jones urged the adoption of the Thomas's splint for transport on the field as early as 1914; that in 1916 considerable numbers of cases were already reaching the casualty clearing stations put up in this splint; and, according to Major Meurice Sinclair ("Fractures," London, 1931) who was in charge of one of the special fractured femur hospitals in France, that the mortality from compound fractures of the femur, which in 1915 was 80 per cent., had been *reduced to 15 per cent. by the following year*, the change being largely due to the "early, efficient, and continuous" use of the Thomas's splint.

The book is well illustrated and very practical, and should be assured of popularity.

THE LANCET

LONDON: SATURDAY, JUNE 15, 1935

THE MEDICAL CURRICULUM

WE publish this week in substance, with the resolutions in full, the report of the special committee of the General Medical Council on the revision of the medical curriculum. The committee was appointed about a year ago to consider various information and proposals received by the Council, certainly over some considerable period, which had for their object the improvement of the educational course; and the Council adopted the report, receiving it as an interim document, and decided that it should be circulated to the licensing bodies and to the deans of medical schools for their observations, when the whole matter will be considered further by the Council at the next session in November, 1935. The profession therefore has not before it a definitive document, but one that records the opinions of the committee in the form of resolutions which are to receive further consideration from bodies and persons directly concerned in the translation of opinions into action, while the views of the different educational authorities have again to undergo scrutiny by the Council as a whole before actual measures of reform will result.

The report confirms the accuracy of much of the criticism of the curriculum which has been rife for many years, although in places the committee indicate where criticism appears to have been ill-founded, certain popular assumptions being made without any, or any complete, warrant. They hold that the fundamental system of our medical education and the methods of its conduct are sound, and that by comparison with the standards of qualification prevailing in other countries our own system is good, and that its improvement can be best advanced by developing and re-shaping it. They find the length of the curriculum, the subjects required, and the order in which they are studied, to need no alteration, and they look towards a more economical use of the statutory period of five years, together with an improved standard at entrance, to remove many objections that have been urged by different authorities and educational centres against some of the present regulations, or, rather, against some of the results that have followed upon their observance. The plea for a shorter educational course, implying the creation of a class of practitioner trained to deal with the routine and emergencies of general practice, receives no mention; the committee have, of course, perceived that any attempt in that direction would be fraught with peril, if only because definition of what such a course should be is impossible. They have had in mind how best to enable the student to cover the ground which modern medicine demands of its followers without extending the present term, and they look to economy in time, to avoidance of overlapping in the studies, and to team-work among the teachers to remove the more obvious defaults, while leaving the teachers with opportunities to give instruction along important lines which to-day are left aside. So far from regarding an abbreviation of the course as an answer to complaints of its severity and expense, the committee have replied to those who in effect are demanding its extension by suggesting how developments in scientific medicine can be met in the curriculum without increasing its length. At certain points more particular indications for reforms would have been welcome, but it must be remembered that the report is an interim one, and that the Council, while it represents all the centres of medical education in the country, has always felt it proper to leave each of those centres great individual discretion as to their methods and domestic work. We may expect from the centres detailed information following upon the general recommendations submitted to them.

An example of where more definite opinion would have been valuable is found in the section referring to biology. Included among the preliminary scientific subjects it none the less cannot or does not receive attention in many of the secondary schools. It has therefore also to be a subject in the medical curriculum proper, and is very rightly placed there in the committee's scheme. But in the resolutions with regard to instruction in anatomy and physiology no special place seems to be allotted to any course in biology as such. Instruction in the subject before registration cannot be made compulsory upon students who have had no opportunities of obtaining the necessary training, but how the untrained student is to make up his deficiency is not alluded to. Information from some of the training centres may assist here in meeting a difficulty. The keeping of the training of students in the same year identical is so convenient that no other procedure can be contemplated, yet with regard to biology the beginners do not start from a common mark. This may seem a small point, but in view of many developments in scientific medicine, it is one worth attention. The general view is endorsed that regular instruction in applied anatomy and physiology should be carried on during the period of clinical studies, and under the instruction of clinical as well as special teachers, an opinion to which the recent report (see THE LANCET, May 18th, p. 1161), being the issue of a conference between representatives of the universities of Oxford, Cambridge, London, and the English licensing bodies, gave particular effect by proposing the formation of a joint board of teachers dealing with the ancillary subjects and pathology so that concerted action might be arrived at. At this point one opinion of the G.M.C. committee will not, we feel, receive general approval. They recommend, dealing with anatomy, that the whole body should be dissected, and many must regard this as unnecessary, and an anomalous suggestion when time is to be found for bringing anatomy into relation with clinical medicine, as is so rightly proposed. That special dissections accompanying research will be made as a matter of course at a later stage by those who are working along special lines is obvious; but remembering the opportunities which the student now possesses for seeing without actually dissecting the details of much anatomical structure, we think that dissection of the whole body is needless, and that many teachers of anatomy will agree with that view. From these teachers definite counsel may be derived as to how the range of their subject can be modified so that needless burdening of memory is avoided and more time found for the acquisition of fundamental knowledge equally useful in future stages of the curriculum and in professional practice. And when the student is bringing the knowledge that he has acquired of anatomy, physiology, and chemistry, under its three headings, to his assistance in the study of pathology, it might be well that pathology should be considered from a rather different angle than that suggested by the report. Pathology is the science of diseased processes on which clinical medicine must be based, while the words of the report imply that clinical medicine is as yet divorced from this science. The words used are meant, probably, to convey that the pathologist instead of concentrating on morbid anatomy should develop his science until it has become an integral and necessary part of clinical medicine. But surely that is what he is doing.

The analysis of the curriculum as given in the report is beautifully clear. Many of the general recommendations for its improvement are those that have been made, some of them over and over again, but they gain force by the endorsement of the central educational authority. Two new recommendations, if acted upon, would render the first stages of professional life far less perplexing to the young doctor while making his services of markedly greater value to the community. It is to be hoped that they will receive support from the various educational centres, as to carry them into effect may not be universally easy. We are referring here to the necessity of the student residing for a certain period within an institution while he is undergoing the later stages of his training, and to the proposal that after qualification he should hold a resident appointment. Both procedures have been advocated in many quarters, and the first is to some extent in actual action; the advocacy of the G.M.C. will be warmly approved. Other passages in the report which point to useful developments in the student's training are the recommendations that the curriculum should include more organised instruction in such subjects as child welfare, pædiatrics, psychology, and radiology. All will recognise that a certain knowledge of the fundamentals of such matters is to-day necessary for the practitioner's equipment.

THE HEALTH AND DIET OF THE SCHOOLBOY

IN most modern resident schools for children of all ages food is provided in ample quantity, though the distribution over the day is sometimes open to criticism, and the proportion of protein, especially first-class protein, to carbohydrate and fat is still often regrettably low. There seems to be an impression among parents that in general boys at preparatory schools are well fed and that the tradition of public schools permits a much lower standard in quality and variety, as well as in cooking and service of meals. The supplementary hamper from home, however, which used to be accepted as almost a necessity, has now become an agreeable incident in many schools, and in some, we understand, is even forbidden. There can be no doubt of the general physical improvement which has followed the greater attention devoted to diet in schools, and not in this country alone. By a careful statistical analysis of the measurements of school-children in Berlin, Dr. GEORG WOLFF has clearly shown that both the school entrants and school leavers in that city have substantially improved in their height and weight over the nine years 1924 to 1932.[1] A similar improvement is to be seen in the English schoolboy according to the extensive observations published by Dr. G. E. FRIEND, the medical officer of Christ's Hospital, Horsham, whose records of growth and diet are more detailed than any previously issued in this country.[2] For instance, in his experience, boys aged 14½–15½ years in the school year 1928–29 were 10 pounds heavier and just over an inch taller than boys of the same ages in 1919–20, while boys of 9½–10½ years were 4 pounds heavier and one-fifth of an inch taller in the later year than their predecessors of 1919–20.

The study of these measurements, analysed under the direction of Prof. MAJOR GREENWOOD, Dr. FRIEND supplements with a detailed inquiry into the diet provided in the school over a period of 20 years, 1913 to 1933, and with a clinical survey made over the same period. Dividing the 20 years into four sections, the food consumption, the physical measurements, and the incidence of disease can be correlated in an interesting manner. In the years 1916–22 there was an average calorific intake of 2780, but the proportion of first-class to second-class protein was relatively low, while, in comparison with previous years, there was a reduction in the proportion of animal fat consumed, and a substitution was made of margarine for butter. During this period the average heights and weights were below the estimated pre-war values (exact pre-war measurements are not available) but, on the other hand, the general health of the boys was good except for a higher incidence of rheumatic affections than in subsequent years. The incidence of fractures was also relatively high in these years. The average number of fractures per year was 6 in 1914–17, 14 in 1918–22, and again 6 in the 11 years 1923–33. The most serious diet deficiences in the middle period were the limitations of the milk-supply and the replacement of butter by margarine, which leads Dr. FRIEND to conclude that the greater fragility of the bones was probably due to a shortage of bone-forming minerals and a deficiency in the supply of fat-soluble vitamins. It would be interesting to know whether this time-sequence of fractures has been observed in other schools. In the last period, 1927–33, the diet has the comparatively high average calorific intake of 3014, derived from 397 g. of carbohydrate, 92 g. of protein, and 108 g. of fat. Larger amounts of butter and milk are now included, the amount of bread has declined but that of sugar has increased. The diet is a generous and well-balanced one but apart from the relatively low incidence of rheumatism, already referred to, the sickness records show surprisingly little variation though, as stated, the physical measurements have much improved.

---

[1] THE LANCET, April 27th, 1935, p. 1006.

[2] The Schoolboy; a Study of his Nutrition, Physical Development and Health. Cambridge: W. Heffer and Sons, Ltd. 1935. Pp. 128. 7s. 6d.

The incidence of colds, fevers of unknown origin, and chills does not appear to be in any way clearly related to changes in the diet, while influenza and the incidence of complications arising from it have increased under the conditions of improved diet. Septic conditions —e.g., boils, impetigo—have also shown a somewhat higher level in the most recent years, and may, Dr. FRIEND suggests, be related to the rising sugar consumption. This is one of the many interesting observations of his study which show the desirability of further investigation on the lines he has adopted. Dr. FRIEND also stresses the value of his records of physical measurements as a clinical aid to the school medical officer. Any boy who is seen to be failing to keep his normal rate of progress is detected, often long before he himself would have reported sick. A failure to show a satisfactory increase in height is usually found to signify little, whilst regression in weight may or may not be important. Regression in the chest grade or in any two grades at the same date is held to indicate an immediate need for inquiry. The most reliable results have been obtained by the use of "time-increment" tables which show weight, height, and chest grades for every six months of age. Dr. FRIEND gives his tables in full and individual examples of their use, and this aspect of his work deserves particular consideration.

A NEW POISONS CODE

THE Pharmacy and Poisons Act, 1933, provided for the formation of a Poisons Board which should be required to prepare a list of substances to be treated as poisons under the Act. This list is referred to in the Act as the "Poisons List." The Act also empowered the Home Secretary, after consultation with the Poisons Board or on its recommendation, to make rules relating to poisons. These rules are termed the "Poisons Rules." The Board held its first meeting in December, 1933, and has now, after many committees and subcommittees, published its report,[1] which contains the Poisons List and the Poisons Rules. The constitution of the Board, to which we have recently alluded,[2] enabled it, with the help of Mr. M. D. PERRINS of the Home Office to whom tribute is paid, to perform a task of considerable difficulty—nothing less than the construction of a new code to replace existing legislation. It was wisely decided that the new code should resemble the present restrictions, but be freed from their defects, and the Board submitted a first draft of provisional proposals to the organisations likely to be affected. The draft received wide publicity in trade journals and was circulated to the police forces. As a result of this extensive consultation many of the original proposals were substantially modified. Its chief function the Board construed to be the utmost reasonable protection of the public from the danger of death or injury from criminal or accidental poisoning. It had to bear in mind the problem of suicidal poisoning, but it was unwilling to include a substance in the Poisons List merely because it might be used as a means of self-destruction, if it carried no real danger of accidental or criminal poisoning. Aspirin is quoted in the report as an illustration. Statistics show that during the period 1925 to 1933 there were 106 fatalities attributed to the taking by suicides of large over-doses of aspirin; it would be unreasonable on this account to schedule aspirin as a poison. Protection of the would-be suicide from himself is beyond the power of legislation; apart from poisoning there are other easily available modes of death.

In the construction of the Poisons List much difficulty was encountered in regard to nomenclature. There has never been a satisfactory definition of the term "poison" upon which to base restrictions; the popular definitions are all either too narrow or too wide for legal use. The report in fact admits that for practical purposes the word is indefinable. Many toxic substances in the list gave trouble to indicate precisely. The list is made as descriptive as possible, terms such as preparations, admixtures, and derivatives being avoided. It contains the well-known older poisons and also many substances of comparatively recent introduction. In Part I. are to be found the dinitrophenols and dinitrocresols which have recently aroused interest as metabolic stimulants. The more powerful endocrine products are represented by insulin and the principles of the thyroid, pituitary, and suprarenal glands. The barbiturates are listed in a short but comprehensively definitive two dozen words. The Board was divided in opinion about the inclusion of Lysol in Part I., and its retention was the outcome of a vote; the reasons actuating the majority and minority are set forth in the report.

The Poisons Rules concern the regulation of the sale and supply of poisons. The power behind them arises from Section 23 of the 1933 Act which allows them to modify the provisions by both anatomy, that the whole body should be dissected, and many must regard this as unnecessary, and an anomalous suggestion when time is to be found for bringing anatomy into relation with clinical medicine, as is so rightly proposed. That special dissections accompanying research will be made as a matter of course at a later stage by those who are working along special lines is obvious; but remembering the opportunities which the student now possesses for seeing without actually dissecting the details of much anatomical structure, we think that dissection of the whole body is needless, and that many teachers of anatomy will agree with that view. From these teachers definite counsel may be derived as to how the range of their subject can be modified so that needless burdening of memory is avoided and more time found for the acquisition of fundamental knowledge equally useful in future stages of the curriculum and in professional practice. And when the student is bringing the knowledge that he has acquired of anatomy, physiology, and chemistry, under its three headings, to his assistance in the study of pathology, it might be well that pathology should be considered from a rather different angle than that suggested by the report. Pathology is the science of diseased processes on which clinical medicine must be based, while the words of the report imply that clinical medicine is as yet divorced from this science. The words used are meant, probably, to convey that the pathologist instead of concentrating on morbid anatomy should develop his science until it has become an integral and necessary part of clinical medicine. But surely that is what he is doing.

[2] THE LANCET, Feb. 2nd, p. 278.

The analysis of the curriculum as given in the report is beautifully clear. Many of the general recommendations for its improvement are those that have been made, some of them over and over again, but they gain force by the endorsement of the central educational authority. Two new recommendations, if acted upon, would render the first stages of professional life far less perplexing to the young doctor while making his services of markedly greater value to the community. It is to be hoped that they will receive support from the various educational centres, as to carry them into effect may not be universally easy. We are referring here to the necessity of the student residing for a certain period within an institution while he is undergoing the later stages of his training, and to the proposal that after qualification he should hold a resident appointment. Both procedures have been advocated in many quarters, and the first is to some extent i actual action; the advocacy of the G.M.C. wi be warmly approved. Other passages in t report which point to useful developments in t student's training are the recommendations t the curriculum should include more organise instruction in such subjects as child welfare, pædiatrics, psychology, and radiology. All will recognise that a certain knowledge of the fundamentals of such matters is to-day necessary for the practitioner's equipment.

under laboratory conditions proved futile. Treatment with permanganate was also disappointing, except in the case of tabellaria, but ozone and activated carbon—in popular language "super-charcoal"—were generally effective. For algal control additions of 0·1 to 0·5 parts per million of copper sulphate have given fair results, but recently a combination of copper, ammonia and chlorine, named for convenience cuprichloramine, has proved to be a more effective algicide. Added to the raw water before it reaches the reservoirs the algæ are killed and sink to the bottom; although without visible means of locomotion they are able while living to remain suspended in water against the effect of gravity. The superiority of cuprichloramine appears to reside in the penetrating property of ammonia which then brings into effect the toxic actions of copper and chlorine, and it would appear quite uncertain whether the liberation of oxygen by chlorine has any lethal effect. The presence, amongst the exhibits, of cuprammonium, which by dilution and chlorination is converted into cuprichloramine, is one of many illustrations of the march of progress, and of the continuous care exercised by the Metropolitan Water Board in the interests of the consumer.

INTERNATIONAL CAMPAIGN AGAINST RHEUMATISM

A LETTER, influentially signed, will be found on a later page calling serious attention to a modest organisation on whose efforts there has followed widespread activity, but which are for the moment embarrassed for want of funds. Communications of this sort are too apt to be looked at askance from the outset owing to the large demands made. A big sum is named, usually to be raised by some capitation fee to be received voluntarily from the mass of the medical profession, and at once the probable failure of the request for subscriptions is seen. Here only immediate need is pleaded, and that is so comparatively small that it ought to be met at once. The International Campaign against Rheumatism was formed in London ten years ago as a league, with the blessing of the Ministry of Health. A conference at which France, Holland, Denmark, Switzerland, Roumania, and this country were represented, resulted in the setting up of a central international council whose duty it should be to distribute the facts and arouse the general conscience to the evils that follow conditions generically termed rheumatism, and to the possibility of abating those evils by organised effort. The *Acta Rheumatologica*, a periodical in three languages, was produced and widely circulated and a small central bureau and library were opened. Important international congresses were arranged with the help of national committees and with the support of representatives of the countries most seriously affected, and in this way examination of many outstanding problems related to rheumatism has been conducted. The expenses so far incurred at the bureau and for the production of the journal, the *Acta Rheumatologica*, have been discharged by personal subscriptions and by contributions from the national groups. But the latter source has largely dried up under the economic conditions under which the world is abiding. It is in the nature of a shock to learn that this policy of abstention has been pursued in this country, which, embarrassed as it may be, cannot plead a position comparable to that existent in the other countries which have hitherto supported the movement. A sum of £1000 is all that is required in the present emergency, while a guaranteed annual subscription of some similar sum would enable the League to pursue efforts which have already been of high practical value. We feel that, when the situation so clearly set out in the letter referred to is realised, the obvious remedy should follow.

PREGNANCY TOXÆMIA UNDER CONTROL

AUTHORITATIVE statements as to how far antenatal supervision can prevent deaths from pregnancy toxæmia are few and far between. It is useful therefore to have a report from Falls [1] on his experience of 500 cases of eclamptogenic toxæmia seen at the universities of Illinois and Iowa over a period of twelve years. While the series is relatively small, it has the advantages of being accumulated under the personal supervision of one man and under one system of treatment. The prenatal care given was simple but thorough, consisting chiefly in examination of blood pressure and urine twice a week from the 28th week onwards. The treatment of the toxæmia itself was orthodox; in the fulminating cases pregnancy was terminated by Cæsarean section, and in others by induction of labour. Such procedures as intravenous injection of magnesium sulphate or glucose were not considered essential. There were only two deaths; indeed, so low was the incidence of eclampsia that Falls almost bewails the fact that he was unable to demonstrate the treatment of this condition to his students once in two years. On the other hand he can congratulate himself on having reduced the mortality in his cases of pregnancy toxæmia to the usual level of mortality among pregnant women in general. That such results are obtainable has often been emphasised in this country, but the rigorous antenatal supervision that should be the rule is still too often neglected, and apathy and indifference are regrettably common.

THE ROME HOSPITAL CONGRESS

THE fourth international congress of hospitals, held in Rome from May 19th to 26th, did some serious work in spite of the distractions of the Eternal City. Six hundred delegates represented 47 nations. The first subject on the agenda was one of the most important, being the hospital as a link in a systematic public health chain, and Dr. J. L. Brownlie's paper, of which we published an abstract last week (he was unfortunately unable to be present) showed where the Scottish health authority is aiming. Later in the congress Dr. A. F. Cooney, who with two colleagues represented the Irish Hospitals Commission, dealt with the cognate subject of the importance of the hospital staff in relation to the community. Hitherto, he said, the advice of the hospital had usually been sought for illness. Now the public health authorities are coming to seek its aid in the prevention and preventive treatment of disease, a change with which hospital policy must reckon. Dr. W. Alter of Syracuse, opening a discussion on the out-patient department, insisted that it should include occupational therapy. The restoration and assurance of the patient's power to work at his calling must, he said, never be lost sight of and never be prejudiced by false romantic views as to light and air. "His occupation should only be changed when it is unavoidable"—a remark in singular harmony with recent correspondence in our own columns. Dr. T. J. Heldt, of Detroit (Mich.), surprised the congress with his assertion that in the addition and subtraction or relaxation of regulations. This section also provided for the regulation of the storage and transport of poisons, and of the containers in which poisons may be sold or supplied; for the manufacture of pharmaceutical preparations containing poisons and for prohibiting the retail sale of poisons except upon a prescription given by a qualified medical, dental, or veterinary practitioner. Hitherto all these matters have been uncontrolled. At every point the motive of restriction is the prevention of criminal or accidental poisoning. In regard to accident, emphasis is laid upon the fact that the principal object of control is to ensure that persons handling poisons are made aware that they are doing so, either by means of a cautionary label or by markings on the container, or by its shape. The rules do almost all that can be done by legislation in this respect, but they cannot guard against want of care or gumption in the home which is the point of greatest danger. The common foolishness of keeping poisons about the house in ordinary bottles and not under lock and key is deplored in the report. One of the saddest features of this form of folly is the toll it takes in the lives of little children, as was pointed out by AIKMAN[3] in a recent paper setting out his experience in America; in the United States more than 500 deaths from acute poisonings (gas excepted) occur yearly in children under five years of age.

---

[1] Falls, F. H.: Amer. Jour. Obst. and Gyn., March, 1935, p. 316.

An important proposal in the rules is designed to abolish the medley of types of so-called poison bottles. It is proposed that the standard bottle shall have its outer surface fluted vertically with ribs or grooves recognisable by touch. The report discloses a feeling among several members of the Board that in regard to certain medicines, notably barbiturates, there should be compulsion to label with the word "poison" or to warn the patient against disregard of prescribed directions. After consideration however it was decided to be inadvisable to depart from the established custom whereby the information given on the container of a medicine does not disclose the name or character of its ingredients—since it is not always desirable that the patient should be cognisant of the nature of the medicament prescribed. The rules include special provisions for the storage and dispensing of poisons in hospitals. These regulations have been anticipated by local rules in the majority of hospitals, but in those where conditions are lax they will serve as a timely and necessary compulsion. Particular importance is attached to the routine inspection by a responsible officer of the poison stores and poison cupboards.

The report is the result of much work in a difficult legislative field. It is clear, and as concise as is compatible with the complexity of its subject. Its object has been to replace existing legislation, criticised by the Departmental Committee as a "patchwork of provisions," and it may be held to have fulfilled this aim.

ANNOTATIONS

MINOR AILMENTS OF LONDON WATER

LAST week in room 4 of the London Government Exhibition at the County Hall was staged the story of how the Metropolitan Water Board ensures a safe supply of drinking water. By an appropriate coincidence this year is the golden jubilee of the regular bacteriological examination of the water-supply of London. This was initiated by Percy Frankland, who adopted Koch's then new plating method for the numerical examination of micro-organisms. The aim of water examination was, he held, to find out if a water is contaminated with sewage. The next advance was the utilisation of *B. coli* as an index of pollution, in America by Theobald Smith, in this country by Klein, in whose laboratory Mervyn Gordon and Houston worked. Gordon studied the *coli* group and classified its varieties; Houston stressed the value of quantitative tests and worked out provisional standards. When he was appointed director he was using a glucose primary medium, the disadvantage being that it required seven days for completion. Then followed the quintuple preferential *B. coli* test, by means of which results were obtained in from three to four days. Finally, in 1928, a presumptive test of the quantitative presence of unconfirmed *B. coli* was adopted, by which tentative information could be acquired in 18 hours and confirmed as above. So much for the detection of dangerous contamination, now under the control of Lieut.-Colonel C. H. H. Harold, M.D. One of his exhibits dealt with the non-bacterial growths in water which although not dangerous to life are a source of perplexity to the water engineer and sometimes of annoyance to the consumer. In August, 1929, Houston wrote a personal letter to a large number of consumers. "I am sorry," he said, "not to have been able to write to you sooner to express my sincere regrets at the inconvenience caused you by the taste of the water supplied to your house. . . . The trouble, due to the decay of harmless vegetable matters, has now been completely overcome, and I feel sure will not recur." The trouble was the growth of an alga, in this case the tufted variety of oscillaria, masses of which had been blown by south-east winds into the outlet of the Island Barn reservoir, and were carried down the main on to the Surbiton works. It was necessary to scour a 54-inch raw-water main, a costly and unpleasant job, and to clean the filter-beds. This is an example of the kind of trouble which has arisen from time to time in river water both from the Thames and the Lee, sometimes the trouble brings complaints of taste from the consumers, but usually simple mechanical clogging of the filters results with greatly added costs of bed cleaning against time and the difficulty of maintaining an adequate supply. In the matter of taste Houston's own feeling was that river-derived waters always have a taste, except perhaps during certain months. People used to say to him, "I like the taste of London water better than any water I have tasted elsewhere." Many algal growths in the reservoirs although capable of taste production may never give rise to a single complaint from consumers. Houston made many experiments to discover remedial measures, but without immediate success. For taste removal he found chlorination useless, and aeration at all events under laboratory conditions proved futile. Treatment with permanganate was also disappointing, except in the case of tabellaria, but ozone and activated carbon—in popular language "super-charcoal"—were generally effective. For algal control additions of 0·1 to 0·5 parts per million of copper sulphate have given fair results, but recently a combination of copper, ammonia and chlorine, named for convenience coprichloramine, has proved to be a more effective algicide. Added to the raw water before it reaches the reservoirs the algæ are killed and sink to the bottom; although without visible means of locomotion they are able while living to remain suspended in water against the effect of gravity. The superiority of cuprichloramine appears to reside in the penetrating property of ammonia which then brings into effect the toxic actions of copper and chlorine, and it would appear quite uncertain whether the liberation of oxygen by chlorine has any lethal effect. The presence, amongst the exhibits, of cuprammonium, which by dilution and chlorination is converted into cuprichloramine, is one of many illustrations of the march of progress, and of the continuous care exercised by the Metropolitan Water Board in the interests of the consumer.

U.S.A. the nervous and mental patient required hospital service greater than that of all other patients put together. There were in round numbers a million hospital beds in the States, and last year a fifth, he said, of all these beds were occupied by patients suffering from one mental disease alone, namely, dementia præcox. He made the shrewd suggestion that this was very likely true of other nations. Some idea of the scope of the congress and of the work of its preparatory subcommittees can be gained in the current issue (January–April, 1935) of the quarterly hospital review *Nosokomeion.* A popular feature of the congress was the exhibition of model of hospitals in Italy, the Italian delegates being anxious to show that Italy is not behind any country in both construction and equipment. There is, it seems, abundant material for international discussion at these gatherings without dissipating power in fruitless controversy. Thus, at the suggestion of Pope Pius XI. the subject of contraception was deleted from the agenda of the congress, and on a motion by a group of Dutch physicians a discussion on sterilisation was excluded from the programme of a particular session. On the other hand Capt. J. E. Stone, secretary of the Birmingham Hospitals Centre, had the satisfaction of getting his system of hospital accountancy adopted in principle. The International Hospital Association will now advise hospitals all over the world to show their expenditure classified under various headings. And then for the first time useful comparisons can be made. The congress was followed by a sight-seeing tour to Naples and Sicily.

ATEBRIN MUSONATE IN MALARIA

MUCH has been said in the lay press about the successful use of Atebrin musonate during the malaria epidemic in Ceylon, and it is interesting to see the first serious medical report on the effects of this new soluble preparation of atebrin. Dr. J. R. Blaze and Dr. A. T. W. Simeons[1] describe it as the atebrin salt of musonic acid—a yellow powder, readily soluble in water, and supplied in dry ampoules each containing 0·125 g. Each dose is dissolved in 3 c.cm. water for intramuscular or intravenous injection, and the amount suggested for intramuscular use is one to three ampoules, and for intravenous injection one ampoule. Of their 21 cases (mostly of subtertian type) 8 had a single intramuscular injection of 0·3 g.; 9 had two injections on successive days, some intramuscularly and others intravenously; and the other 4 had oral atebrin as well. The paper is illustrated with 21 charts, and it is clear that they represent the clinical effects of this treatment: in some the temperature dropped immediately; in others there are two, three, and sometimes four subsequent attacks of pyrexia, as might be expected. Similar charts, however, can be obtained with intramuscular quinine, or may even be paralleled in cases receiving no treatment at all. What we really require therefore is evidence of the effect upon the parasite, and here Blaze and Simeons's paper is again rather unsatisfactory. A single injection of 0·375 g. atebrin musonate is followed by temporary disappearance of the parasite, but this was not always seen in heavy malignant infections. Two injections of the same dose, given on two successive days, seem to control the temperature within 48 hours and to cause disappearance of both forms of parasite within four days; but crescents (gametocytes) do not appear to be influenced in any way. In some cases the ring form of the parasite reappears within a few days, but it is said that they disappear again spontaneously. On the whole it is thought that the intravenous route, though harmless, is less satisfactory than the intramuscular. Blaze and Simeons are satisfied with the immediate results of the treatment; but they agree that the period of observation has not been long enough for a comparison of the relapse rate of atebrin musonate with that of oral atebrin or quinine. It is hardly conceivable, with this evidence in front of us, that a massive malaria infection can be entirely eliminated from the body by means of two comparatively small injections of this admittedly potent antimalarial drug. The histories of all other protozoal blood infections suggest that much more prolonged and intensive therapy will prove necessary. It is a relief, however, to know that this new method is comparatively harmless and has no disagreeable effects.

INTRAVENOUS PITUITRIN IN OBSTETRICS

THE popularity of pituitrin in obstetric practice has varied during the last two decades. In most patients its administration leads to a fairly uniform increase in the number and strength of the uterine contractions, but sometimes this increase does not take place and the uterus goes into spasmodic contraction or the patient rapidly enters into a state of profound surgical shock. Smaller doses and slower administration have been shown to lessen the risk of both these complications, and accordingly it is surprising to find Baron[1] of Montreal recommending intravenous injection, albeit in minute doses. Zorn in 1926 first described this method, and maintained that quantities as great as 0·25 c.cm. were safe. Baron advises doses of one minim, and reports that when the drug was thus used to aid induction of labour following rupture of the membranes, the first contraction appeared soon, lasted about six minutes, and after an interval of 20–30 seconds was followed by a second lasting two to three minutes. This in turn was succeeded by good strong and regular pains in all but 1 of 55 cases. The drug was also used in this manner with success in 9 cases of "tired uterus," and in 15 cases the low application of the forceps was obviated. Clearly the outstanding advantage of this method is its certainty of action. But the series of cases reported is too small to carry much conviction and by no means proves it free from the danger of pituitary shock or rupture of the uterus.

MINISTERS OF HEALTH

THE reconstitution of the Cabinet last week has sent Sir E. Hilton Young to the House of Lords and filled his place at the Ministry of Health by Sir Kingsley Wood. Nine years ago Sir Hilton was nominated by the Crown as the first layman ever to sit on the General Medical Council, and for more than four years he placed his many gifts and attainments at its disposal. It is on record that in asking for more Crown nominations to the Council a Member of the House of Commons took it for granted that "one layman could not possible fill his rôle adequately if alone amongst 37 other medical members." Sir Hilton filled his rôle at the Council's board, and for three years as a member of the executive, in a way which did much both to increase the confidence of the public in the General Medical Council and to procure the respect of his medical colleagues. He resigned from the Council on becoming Minister of Health and this three and a half years' tenure of this office have witnessed a revolution in public health practice, for a new standard of housing has been set up providing for the separation of the sexes over ten years of age and space for the increasing family, while a date has been fixed after which it will become an offence for either landlord or occupier to overcrowd a house in excess of its legal standard. By arduous tours through the country Sir Hilton came personally into contact with the medical officers of health on whom the execution of this programme will so largely rest, and now it will fall to his successor to see the scheme for abolishing slums put through. But in the House of Lords Sir Hilton will find many opportunities of using his great knowledge of public health and his interest in the lives of the people.

---

[1] Indian Med. Gaz., April, 1935, p. 185.

[1] Baron, H. A.: Jour. Obstet. and Gyn. Brit. Emp., April, 1935, p. 322.

Sir Kingsley Wood, who leaves the post office to be Minister of Health, is no stranger to the department, for he served as Parliamentary Secretary some years ago. He has another practical qualification for the insurance side of the work, since he was one of the original members of the London Insurance Committee, and became its chairman for the year 1917–18, receiving the honour of knighthood during his year of office. Sir Kingsley is a solicitor and his firm has for many years been associated with one of the largest industrial approved societies. In the early days of the scheme he paid special attention to the problem of the adequacy of the medical service for the insured population in London, and sanatorium benefit, which at that time was administered by insurance committees, also received his intensive consideration.

SPEED LIMIT FOR DOCTOR'S CAR USED AS AMBULANCE

MEDICAL practitioners, along with all other motorists, are being summoned for exceeding the speed limit of 30 miles per hour imposed by the Road Traffic Act of last year. A doctor who said he was hurrying to an urgent maternity case found the magistrates in a lenient mood. Where a patient is being taken in emergency to surgery or hospital by motor-car, there is a possible exemption under Section 3 of the Act. In somewhat verbose language the section declares that the provisions of any enactment, statutory rule or order which impose a speed limit shall not apply to any vehicle on an occasion when it is being used for fire brigade, ambulance, or police purposes, if the observance of those provisions would be likely to hinder the use of the vehicle for the purpose for which it is being used on that occasion. Last April a doctor arranged to drive a patient of hers to a maternity home as soon as necessary. She was sent for one day and, as soon as she saw the patient, she realised it was an urgent case. She had to drive 12 miles to the home, and in traversing a built-up area she was said to have travelled between 38 and 40 miles an hour over six-tenths of a mile. For this the Tunbridge Wells magistrates fined her £2. She appealed to the West Kent Appeals Committee—i.e., to quarter sessions. Police witnesses said that the saving of time by the excess speed was only one minute. On the other side, it was proved that the patient's medical adviser had pronounced the case to be one of great urgency, that the patient had to be assisted from the car on arrival, and that the child was born within an hour of the mother being admitted to the home. In the mother's condition, it was said, any further time in the car would have precipitated matters. The Appeals Committee allowed the appeal and, although the decision of quarter sessions upon a particular set of facts is not as weighty as a ruling by the High Court, the result is a useful precedent. To come within the exemption of Section 3 the car must be "used for ambulance purposes," and the case must be one where reduction of speed to 30 miles would hinder those purposes. The best rate of speed to minimise the jolting of an injured patient is a question which the magistrates might need expert evidence to decide.

THE BLINDING FILARIA IN EAST AFRICA

ONCHOCERCIASIS has appeared in East Africa and there is little doubt that it is taking the blinding form whose devastating effects in the Belgian Congo and the Sudan were noted in our issue of June 1st. P. G. Preston has reported [1] from Kenya onchocerca nodules, steadily increasing for two years and proved to be such by microscopic examination after excision. They were taken from a man who, except for service as a porter in the King's African Rifles near Kilimanjaro during the late war, had always lived in the Kisii Reserve. From time to time he had suffered from pain as if a knife were thrust behind the eyes, with periodic blurring of the vision, which latterly seems to have become permanent. Preston believes this to have been the first case of onchocerciasis microscopically identified in Kenya. Further, A. J. Boase [2] reports from Uganda the case of a Muganda with ciliary congestion, posterior synechiæ, and a hazy cornea through which the fundus could not be seen; the corneal microscope revealed microfilariæ judged to be a third of a millimetre long. The man had *Mf. perstans* in the blood, but the size of the corneal microfilariæ was that of the larvæ of *Onchocerca volvulus* and not of *Acanthocheilonema perstans*, while the ocular condition corresponded to that produced by onchocerca. There is thus grave reason to fear that East Africa is threatened with an encroachment by the blinding filaria.

LEGACIES AND GIFTS FROM PATIENTS

"No practitioner is safe against becoming involved in costly litigation arising out of his practice" is a well-worn sentence in the report of the Council to the general meeting, held last Wednesday, of the members of the London and Counties Medical Protection Society. It is a statement which hardly needs making to members of such a society, but one to which heed should at once be given by those—now happily few—who have not joined one of the societies formed to protect their interests. The report contains much to show how watchful is the council of this society over the old recurring difficulties of professional life and the new difficulties which are constantly arising. A fortnight ago (p. 1296) we dealt with the claims against a deceased practitioner's estate opened up by a legislative Act of 1934. The report contains also a timely reference to the legal difficulties which may arise where a doctor accepts a gift from a patient. Their confidential relationship sets up a legal presumption of undue influence unless it can be shown that the patient received independent advice. Another point of the general law appears to be imperfectly appreciated. If a medical man is asked to witness the signature of a patient's will, his attestation makes void any legacy which the patient may have left to him. The law insists that, if the attesting witness (or his or her wife or husband) is the sole beneficiary under a will, then the will is invalidated altogether. If the witness (or his or her wife or husband) is only one of the beneficiaries under a will, then the will stands valid except as regards the benefit intended for the witness (or his or her wife or husband) while the latter benefit becomes, in the words of section 15 of the Wills Act of 1837, "utterly null and void." It is believed that these rules of law are not taught to medical students, and there is much value in the suggestion that such matters should be included, with other legal principles affecting professional relationships, in the curriculum of the medical schools. A practitioner is placed in an invidious position if he is called upon to rebut the legal presumption of "undue influence" when the executors of a deceased patient, in the course of their duty to the patient's estate, are obliged to challenge some gift made by the patient to his medical attendant several years earlier.

THE THYROID AND THE CIRCULATION

A BROAD survey of the contrasting circulatory changes in hyper- and hypothyroid states has been undertaken by F. Kisch.[1] In describing the tachycardia, increased minute volume of cardiac output, and increased speed of the circulation which are found in thyrotoxicosis, he is on ground where there is general agreement. But his account of the way in which the altered thyroid secretion brings about these changes seems to leave solid earth behind. After quoting experiments in support of the theory that the thyroid hormone exerts its influence on the heart only through the cardiac nerves, he suggests that the stimulus originates in the action of the thyroid secretion on the vegetative centres in the mid-brain. No definite explanation is offered for the occurrence of auricular fibrillation and flutter, but it is thought they may be due to "severe damage to the cardiac musculature." Against this is the strong objection that normal rhythm often returns within a day or two of thyroidectomy, which makes it seem that the change in the muscle is functional and not (as Kisch's phrase implies) organic. The latter part of the paper reviews the changes in the circulation in myxœdema. The statement that this condition occasionally causes gross circulatory failure has been seriously questioned since the introduction of complete thyroidectomy as a method of treating intractable heart failure; the artificial hypothyroidism thus produced has been shown to have a favourable effect on the symptoms of gross heart failure—even despite the further slowing of the circulation-rate and increase in the size of the heart.

MEDICINE IN BERKSHIRE

IN a modest preface the editors of the third volume of the *Royal Berkshire Hospital Reports* (10*s.* 6*d.*) explain that their aim is to record important cases observed in the hospital and to give to doctors in the area it serves particulars of the facilities offered for diagnosis or treatment. The outcome of their efforts is, however, of much more than local import, for not only are some of the individual cases of rare interest but the critical surveys of certain diseases—notably a review of 56 cases of anæmia admitted to the hospital between 1928 and 1934, by Dr. J. Mills and Dr. R. Herring, and a study of 71 consecutive operations on the thyroid gland by Mr. J. L. Joyce and Mr. F. H. Aitken Walker—chronicle experience which should find a permanent place in the literature of the subjects. The complete tables supplied by Mills and Herring, giving details of blood picture in each case at various dates as well as results of examination for biliary function, achlorhydria, achylia, and C.N.S. symptoms, provide records of great value in relation to the form of treatment given and the reticulocyte response. The general conclusions reached by these authors from their material were set out in their communication to THE LANCET three months ago; they emphasise (1) the advantages of the intramuscular route for liver therapy over the oral route and (2) the necessity for continuous treatment after recovery. The advice sometimes given "to have a rest from liver" is strongly condemned, and the desirability of the control of treatment by regular blood examinations is made clear. Mr. Joyce reports that of the 45 toxic cases in this goitre series 32 have been able to return to a normal active life, but the series shows an operative mortality (5 deaths) that the authors consider capable of improvement by earlier operation and closer coöperation between practitioner, physician, and surgeon. There are at the Royal Berkshire Hospital no facilities for estimation of basal metabolic rates and the authors hint at the desirability of the provision of these facilities. It seems justifiable to ask for them in a hospital which has installed such modern equipment as a deep X ray therapy plant and a clinic for the treatment of squint. The members of the staff in charge of these developments are respectively Dr. Paul Cave and Mr. G. T. Willoughby Cashell, each of whom contributes an article to the *Reports* discussing the scope of their work at the hospital. Other general articles include a review of some cardiac cases presenting features of interest, by Dr. Gordon Lambert; a discussion of the causes of loss of consciousness following acute head injury and their relation to the treatment of this condition, by Mr. R. Q. Parkes; a description, with comments, of four cases of brain abscess of otitic origin, by Mr. Leslie Powell; and a short analysis of the literature on peptic ulcer of Meckel's diverticulum, with two new cases, by Mr. Joyce. Of the individual cases the most remarkable is that described by the chief editor of the *Reports*, Dr. H. S. Le Marquand, with a pathological report by Dr. Dorothy Russell. In this case, on which we shall have occasion to comment, precocious puberty in a boy was associated with a tumour in the floor of the third ventricle.

That these *Reports* do not reflect an exceptionally fertile period but rather provide a fair sample of the normal activities of the hospital is clear to those who recall the quality of the work published in previous volumes (1932 and 1933). It is unusual that such good use is made of the clinical and pathological material available at a hospital not attached to a teaching school; it is even more rare to find team-work so well established as to enable its results to be collected and produced periodically with well-chosen illustrations in handy volumes.

SIR Frederick Banting, F.R.S., will deliver an informal address on the History of Insulin at the British Postgraduate Medical School, Ducane-road, London, W.12, on Thursday, June 20th, at 2 P.M. Medical practitioners are invited.

THE council of the Royal Society of Medicine on May 21st decided to make the first award of the Hickman medal to Dr. Wesley Bourne, anæsthetist to the Royal Victoria Hospital, Montreal, and lecturer in pharmacology at McGill University. Dr. Bourne paid visits to this country in 1926 and 1932, and has contributed to our columns pioneer observations on vinyl ether and cyclopropane anæsthesia.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LVI.—PROGNOSIS OF SIMPLE MOLES AND MELANOTIC SARCOMA

THIS article will attempt an answer to the following questions:—

1. What is the risk that a congenital pigmented mole may become malignant?
2. What are the factors that may increase the risk?
3. What is the outlook in untreated melanotic sarcoma?
4. What are the chances of cure in melanotic sarcoma?

The Simple Mole

Risk of malignancy.—There are few people who do not carry about from birth and through life one or more pigmented moles. On the other hand, melanotic sarcoma is a rare disease and so is squamous-celled carcinoma starting in a mole. It follows that the risk of malignancy in a simple mole is a small one. The chances against it are at least some thousands to one.

Factors favouring the onset of malignancy.—Chronic irritation, more rarely a single acute trauma, and unwise irritant treatment are the main causes of malignancy in moles. Moles subject by their situation to constant friction—for example, upon the neck where the collar rubs them, near the anus and upon the inner side of the thigh, or at the waist in women—are liable to malignancy. Undue exposure to sunlight may produce either melanotic sarcoma or epithelioma in a mole, and consequently these conditions are commoner in Australia than in this country. Queensland farmers have given up keeping white cattle because of their liability to cancer of the skin. In parti-coloured animals the cancer always develops on the white or unprotected portion of the hide.

Signs of threatened malignancy.—The signs which indicate the onset of malignancy in a mole are bleeding, increase of size, increase of prominence above the general surface, enlargement of glands, and they are unaccompanied by pain. Melanotic sarcoma is so rare that few men in practice have much experience of it. It follows that even if a patient with an active and threatening mole does seek advice early, he is liable to be met by reassurances, or the mole may be treated by the application of a caustic, an almost infallible method of inducing malignancy in a previously innocent mole.

Treatment.—Moles which are showing the signs of activity I have mentioned, or which are situated in regions where they are liable to irritation—e.g., the inner side of the thigh, the anal region, or the neck at the level of the collar—should not be merely watched, or irritated by ineffective treatment. They should be cut out with a small margin of ¼-in. of healthy skin and the incision sutured. The removal should expose the subcutaneous fat. The tissue removed should be microscopically examined in case by any chance malignancy has been overlooked, for it has to be remembered that the onset of malignancy in a mole is sometimes unaccompanied for a time by any striking alteration in the appearance of the mole. This is one of the difficulties of the subject, and should not be overlooked.

The manufacture of melanotic sarcoma from a mole by the application of a caustic is often due to the patient's initiative, but it must be confessed that more often his medical adviser is responsible. It cannot be stated too strongly that under no circumstances should a caustic be applied to a mole. The practice is not extinct, for recently I heard of a case in which a patient had undergone this treatment for a group of three moles. Other irritant forms of treatment such as the application of carbon-dioxide snow are almost equally dangerous, and so too is partial or careless excision or ligature. It is questionable whether even for the smallest mole diathermy or electrolysis is advisable. These agents are only safe if complete destruction at one sitting can be guaranteed. Methods of treatment of moles by caustics, partial excision, or ligature amount to experiments in the conversion of innocent into malignant tumours.

Melanotic Sarcoma

The outlook in untreated cases.—It is customary to speak of melanotic sarcoma as the most malignant of known tumours. It is certainly not the most rapidly fatal. The average duration of a case of melanotic sarcoma is about three years, and up to within a few months of the end the patient remains free from pain and able to get about. The factors producing disability are ulceration and hæmorrhage from the primary growth and its secondary deposits in the skin, great enlargement of the liver, and œdema and lymphatic weeping of a limb, the lymphatic vessels of which have been blocked by permeation. The spread of the disease takes place, mainly and at first exclusively, through the lymphatics, and the glands accordingly soon become enlarged. Blood-dissemination is a late event and may be absent nearly to the end. Accordingly melanuria is a late symptom.

Frequency.—Though melanotic sarcoma is fortunately a rare disease, it is not on that account to be neglected. I am indebted to Dr. Robert Greenough for the information that in the ten years 1917–26 inclusive 64 specimens of melanotic sarcoma were examined by the Diagnosis Service of the Massachusetts Department of Public Health. The population from which these specimens were derived numbers between three and four millions. Probably in only a minority of cases was a specimen sent for report, and rare though the disease is, the figures show that it deserves more careful attention from the profession than it has hitherto received.

Treatment.—Melanotic sarcoma has the reputation of being an inevitably fatal disease, for which surgical treatment offers at best a forlorn hope. There are various reasons for this pessimistic attitude. It is still generally thought that the growth obtains early access to the blood stream and spreads mainly if not entirely by the blood-vessels. If this were true, operative treatment is obviously useless, but as I showed many years ago, blood dissemination is a terminal, not an early event. The early stages of dissemination are by permeation of the lymphatic system around the primary growth, combined with lymphatic embolism of the corresponding set of glands. These glands form a barrier or filter which for some time arrests further the spread of the disease. Even at the time of death the distribution of the secondary deposits may be such as to show that they all arose from local centrifugal lymphatic spread. For instance, in a melanotic sarcoma of the hand the secondary growths were found only in the corresponding limb and the corresponding lung, all the rest of the body being free of the disease. All the evidence shows that the spread of the disease is at first local only, and that it should be amenable to surgical treatment.

Fifty years ago it was, I believe, quite usual to excise a carcinoma from the breast without removing the whole breast. The recurrence-rate at that time approached 100 per cent. Even as late as 1887 Mitchell Banks met with little support when he advocated the removal of the whole breast and the routine removal of the axillary glands. Since that time, as the result of pathological researches into the mode of spread of the disease, the operation for breast cancer has been gradually rationalised, and though many cases still reach the surgeon far too late, the results of treatment have improved enormously. At the present time 56 per cent. of cases treated on scientific lines remain free from recurrence three years after operation.

In respect to melanotic sarcoma, there is a very different and a very depressing story to tell. Even when melanotic sarcoma is recognised, it is often considered that a mere limited excision of the visible disease will meet the case, and no thought is given to its spread by permeation in the deep fascia, or to the probability that the lymphatic glands even if not enlarged may already be infected. The methods used are similar to those employed in breast cancer forty years ago. Since both diseases spread by early embolic invasion of the lymphatic glands and centrifugal permeation of the deep fascia, it is not surprising that the surgical results of excising melanotic sarcoma to-day approximate to those obtained in breast cancer in the primitive period, that is to say, the recurrence-rate verges on 100 per cent. Neither is it surprising that melanotic sarcoma has the reputation of being perhaps the most malignant of tumours.

In these matters surgical methods have not kept pace with pathological knowledge. The mode of spread of melanotic sarcoma has been accurately studied and an operation which fulfils the requirements of pathology is surgically possible. It is necessarily a severe operation but not a dangerous one. The requirements are the removal of:—

1. A circle of skin at least 2 inches in diameter centred on the primary growth.
2. A circle of deep fascia 4 to 6 inches in diameter centred on the primary growth.
3. An area of muscle immediately beneath the primary growth.
4. A band of deep fascia carrying the trunk lymphatics from the primary growth to the nearest glands.
5. The set of lymphatic glands immediately above the primary growth, together with a circular area of deep fascia surrounding them, and likely to be permeated.
6. The set of glands immediately above the first set of glands, if these latter are obviously enlarged.
7. All these parts in one piece.

In pathological language the object of the operation is the removal intact of the permeated area of the lymphatic system, of the embolically invaded glands, and of the trunk lymphatics connecting them.

Results.—If melanotic sarcoma were treated on these lines there is no reason why our results should not be at least as good as those secured in breast cancer. When once blood dissemination has begun, I admit that no surgical operation is likely to be successful. But blood dissemination is a very late event, and in some cases of the disease it is almost absent nearly to the end.

I cannot produce much direct evidence that a scientifically planned operation for melanotic sarcoma will cure the disease, for rarely in my career have I had its treatment from the beginning. With about two exceptions all the cases seen by me have been recurrent cases in which a local excision or cauterisation of the primary growth has been followed by local recurrence and gland enlargement. Eight or ten cases in all, apart from hopelessly inoperable ones, have thus come under my care. Unpromising as was the material, I have had among these cases three successes. One of them died from cardiac disease without recurrence 18 years after operation, another was known to be well 3½ years after operation, when she was lost sight of, and a third patient remains well to-day.

Melanotic sarcoma has not the great importance of the commoner forms of malignant disease. But that is no reason why its treatment should still be conducted on the ineffective lines handed down from our forefathers and by methods which are relics of barbarism.

SAMPSON HANDLEY, M.S. Lond., F.R.C.S. Eng.,
Senior Surgeon to the Middlesex Hospital.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. H. H. Babington to *Pembroke* for R.N.B.

Surg. Lt.-Comdrs. E. E. Malone to *Victory* for R.N.B.; J. J. Keevil to *Royal Sovereign*, addl., and vice Brown, temp.; and D. R. F. Bertram to *Pembroke* for R.N.B.

Surg. Lts. B. S. Lewis and F. W. Chippindale to *Winchelsea*, L. G. Yendoll to *Victory* for R.N.B., and B. S. Lewis to *Cricket*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. C. Mason promoted to Surg. Lt.-Comdr.

Surg. Lts. J. L. Cox transferred from List 2 of the Severn Division to List 2 of the London Division, and A. W. Kendall to *Pembroke* for R.N. Hospital, Chatham.

E. J. S. Woolley entered as Proby. Surg. Lt. and attached to List 2 of the London Division; and R. E. King entered as Proby. Surg. Sub-Lt. and attached to List 2 of the Clyde Division.

ROYAL ARMY MEDICAL CORPS

Short Serv. Commissions.—The undermentioned Lts. to be Capts.: W. M. E. Anderson and H. B. Wright.

The undermentioned Lts. to be Capts.: R. H. Foster, F. E. Buckland, J. H. J. Crosse, D. T. Swift, J. Boyle, E. H. P. Lassen, I. Buchanan, A. L. Pennefather, J. S. Ruddell, and W. T. Bermingham.

REGULAR ARMY RESERVE OF OFFICERS

Maj. A. M. Benett, having attained the age limit of liability to recall, ceases to belong to the Res. of Offr.

TERRITORIAL ARMY

Capt. G. A. Macdonald resigns his commn.

C. E. Moorhead to be Lt.

ROYAL AIR FORCE

Flight Lt. C. J. S. O'Malley is promoted to the rank of Squadron Leader.

AUXILIARY AIR FORCE

No. 607 (County of Durham) (Bomber) Squadron: Flying Offr. D. A. Smith is promoted to the rank of Flight Lt.

INDIAN MEDICAL SERVICE

Majs. to be Lt.-Cols.: P. R. Vakil, J. L. D. Yule, M. L. Dhawan, and B. S. Dhondy.

Capt. K. R. Sahgal to be Maj.

The undermentioned officers have vacated appts. in India:—

A.D.M.S.—Lt.-Col. F. Worthington, D.S.O., O.B.E., R.A.M.C.

D.A.D.M.S.—Lt.-Col. A. C. Macrae, I.M.S.

D.A.D.H.—Maj. W. W. S. Sharpe, R.A.M.C.

The undermentioned appts. have been made in India:—

D.A.D.M.S.—Lt.-Col. B. C. Ashton, I.M.S., and Maj. T. J. L. Thompson, M.C., R.A.M.C.

D.A.D.H.—Maj. T. Young, R.A.M.C.

Indian Medical Department.—Maj. (Sen. Asst. Surg.) H. J. J. Fordham retires.

SPECIAL ARTICLES

GENERAL MEDICAL COUNCIL

REPORT OF THE CURRICULUM COMMITTEE

THE Curriculum Committee of the General Medical Council was appointed in June, 1934, to consider information and proposals received by the Council in respect of the revision of the curriculum. The members of the Committee were Dr. H. L. Tidy (chairman), Dr. J. B. Leathes, F.R.S., Prof. J. S. B. Stopford, F.R.S., Sir George Newman, Dr. H. G. Dain, Mr. L. P. Gamgee, F.R.C.S., Prof. R. J. Johnstone, F.R.C.S., with the president as an ex-officio member. The report, considered as an interim document, was presented to the Council on May 31st, and it was resolved that it should be circulated to the licensing bodies and the deans of the medical schools for their observations, when the whole matter would be further considered at the November session.

A full abstract of the recommendations forming the report follows with the resolutions given verbatim :—

I.—Admission and Registration

Before admission to the medical curriculum proper the present Resolutions of the Council require that a student shall have passed an examination in general education and an examination in preliminary scientific subjects, and should be registered as a medical student. The curriculum proper may be taken in general as commencing with the study of anatomy and physiology. Registration as a medical student by the Council takes place at this point, but not under the age of 17 years. The average age at registration is now about 18 years, and the Committee are in agreement with the opinion that the medical curriculum proper should not be entered upon before that age.

Registration of medical students is not mentioned in any of the Medical Acts, and could only be enforced by the Council if Parliamentary powers or general consent were obtained, but the Committee recommend that all the licensing bodies should be invited to decide to raise the age of admission to the curriculum proper to 18 years, and also to require registration.

GENERAL EDUCATION

The present policy of the Council is that the standard of general education should be at least equal to that of entry into other learned professions, and not below that of the matriculation examination of universities. The Committee are in agreement with the widely expressed desire that the general education required of the student should not cease at too early an age, and also that the present standard should be raised, and not only by the addition of further subjects.

It would be difficult to formulate a scheme capable of general application. Many boys and girls now take the school certificate about the age of 16 years, and having then decided to enter the medical profession, complete their study of the preliminary scientific subjects while still at school. They are thus in surroundings where they can continue the study of other subjects, and, we hope and believe, frequently do so. In such conditions there would be no great difficulty in arranging that a subsequent examination should be taken in one or two additional subjects of general education at a fairly high standard. Such an arrangement cannot, however, apply to all students, since the conditions under which the examinations in general education and preliminary scientific subjects are passed vary considerably under different licensing bodies and with individual students. The Committee are of opinion that if the principle be adopted, the licensing bodies will themselves most appropriately find the method of applying it to their own requirements. At the pre-registration examination, which at present consists of scientific subjects, one or two subjects of general education at an approved standard should also be taken.

PRELIMINARY SCIENTIFIC SUBJECTS

Many secondary schools are now well equipped for teaching the preliminary scientific subjects, especially chemistry and physics. As great expense has been incurred as a result of the Council's Resolutions of 1922, there would be hardships if any change in principle in regard to chemistry, physics, and biology should be made. The position varies greatly in different places, and some medical schools must continue to teach these subjects, and many prefer to do so.

Chemistry.—Much of inorganic chemistry possesses no special educational merit and is not of particular value in the medical sciences; the omission of such matter would enable both inorganic and organic chemistry to be taken in this elementary course and examination, and the Committee therefore recommend that the subject of chemistry should include both inorganic and organic chemistry. A student would thus pass about the age of 18 an examination which would satisfy the requirements of the Council in chemistry and physics, and enable him to enter on the curriculum proper without having before him any further examination in these subjects.

Biology at present is not commonly taught in secondary schools, even in many of those satisfactorily equipped for the teaching of chemistry and physics, although considerable advance is in progress as the result of the Council's Resolutions. They hold that knowledge of this subject is a valuable introduction to anatomy and physiology, and that instruction in biology should not cease at the end of the pre-registration period. The Committee recommend that it should be permissible, as at present, for the course of instruction to commence before, but that the examination should be taken after registration. They recommend that it should be regarded as the intention of the Council that instruction should continue into the period of the Professional Scientific Subjects, and that the examination should not be taken immediately after registration. Botany should be considered as included in biology.

II.—Medical Curriculum Proper

The subjects of the curriculum proper fall into two main groups and periods of study, the Professional Scientific Subjects occupying the first two years, and the Clinical Subjects occupying the final three years. The definite "block" which exists at present between these two periods has evoked numerous criticisms. A study of the Council's Resolutions and the Additional Resolutions shows that it was the intention that there should be an examinational block at this point, the object being that the student should not pass to the three clinical years until he had proved his knowledge in the Professional Scientific Subjects. Of this type of block there is no substantial criticism, and the Committee are of opinion that it should be maintained. It was plainly not the intention of the Council that the block should be concerned with instruction. The Resolutions and Additional Resolutions were framed so as to avoid this by providing for instruction in applied anatomy and physiology during the clinical years. But it is clear that such provisions are insufficient to achieve adequate correlation of the two groups. The student has no introduction to clinical studies in the first two years, and having passed the examination at this stage, he may hear little more of anatomy and physiology till he meets anatomy in the final surgical examination. There may be no effective correlation of the two groups of subjects and the student, having passed the examination, may forget details which should form the foundations of clinical teaching and knowledge.

The Committee recommend, first, that an introduction to clinical subjects should take place during the period of study of the Professional Scientific Subjects, and secondly, that organised instruction in applied anatomy and physiology should be continued during the Period of Clinical Studies.

A.—Period of Study for the Professional Scientific Subjects

The Committee endorse the common view that the total duration of the study of the Professional Scientific Subjects should remain at two academic years. But they hold the Council should approach the licensing bodies with a view to an increase of the length of the terms of study.

[The various subjects are then referred to separately.]

It was resolved that instruction in *biology* should continue during these two years, an examination to be held at some appreciable interval after registration, but that no special instruction or examination in *organic chemistry* would be required if it has been duly dealt with as a pre-registration subject.

Anatomy.—The Committee refer to criticisms, general and special, on the teaching of anatomy which suggest that the subject instead of being taught on a vocational basis is sometimes conducted on the assumption that all students are likely to become professional anatomists. These criticisms the Committee did not find substantiated with regard to all the teaching schools, and held that the matter was one for the internal administration of the various teaching bodies.

Physiology.—The criticisms of the teaching of physiology were found to be generally on the same lines as those on the teaching of *anatomy*, but less emphatic. Some critics hold that too much attention is paid to branches of physiology which are of little vocational value, while others suggest that modern physiological developments of practical importance are not sufficiently promptly incorporated in the teaching. The Committee are of opinion that physiology and clinical medicine should be brought into closer union by continuing the instruction in physiology into the clinical years and by the association of clinical teachers with the teaching of physiology.

The Committee accordingly recommend that the resolution with regard to anatomy and physiology should read as follows :—

> "*Human Anatomy and Human Physiology.* These courses should include : (1) dissection of the entire cadaver ; (2) anatomy of the living body ; (3) elements of human embryology ; (4) histology, cytology, and the principles of genetics ; (5) the principles of general physiology, the chemistry and physics of bodily functions studied as far as possible in the human subject ; (6) elements of normal psychology."

The Committee further recommend that the following resolution should be included in the resolutions applicable to the teaching both of medicine and of surgery in the Period of Clinical Studies :—

> "Regular instruction and demonstrations in applied anatomy and physiology during the Period of Clinical Studies, to be carried out by the teachers of anatomy and physiology and the clinical teachers jointly."

INTRODUCTION TO THE CLINICAL SUBJECTS

The Committee accept the view that the introduction to the Clinical Subjects should take place during this period, with the object of associating them with the Scientific Subjects as early and as closely as possible, but at the same time they consider that the efficient teaching of the Scientific Subjects must be properly safeguarded. Consequently they recommend that the introductory Clinical Subjects should be taught throughout, but not before, the second year, and that the amount of time allotted to them should not exceed one-third of the total time available in that year.

With these essential provisos, they recommend that the following subjects should form part of the curriculum for this period :—

(1) Elements of the methods of clinical-examination, including physical signs, the use of stethoscope, ophthalmoscope, &c., and the examination of body fluids (with demonstrations on living subjects, normal and abnormal); (2) an introduction to general pathology ; and (3) to *pharmacology*.

The Committee accept the view that a student should not pass to Clinical Studies until he has satisfied the examiners in the subjects of the first two years.

B.—Period of Clinical Studies

The clinical period should begin in the third year of the curriculum and occupy the third, fourth, and fifth years and following the foregoing recommendations the student should already possess some knowledge of elementary pathology and bacteriology.

[The Committee refer to certain general criticisms before passing to individual subjects.]

1. *Full Use of Time Available.*—The Committee demur to the length of the long vacation and other holidays, and hold that during the three calendar years of the clinical period instruction should be continuous with reasonable breaks and cessation of systematic lectures during the academic holidays. They recognise that all the licensing bodies cannot conform exactly to one rule, and suggest that the total period of time should be from 33 to 36 months.

2. *Teaching of Anatomy and Physiology.*—Regular instruction in applied anatomy and physiology should be carried on during this period jointly by teachers of these subjects and of the clinical subjects.

3. *Closer Contact of the Students with Patients.*—The Committee are of opinion that this could be best secured by a period of residence in hospital. In those teaching schools in which such residence is available at present, it is found that the students can be allowed valuable responsibility under satisfactory supervision. They recommend that there should be a period of not less than one month's residence in hospital, both in medicine and in surgery, and that the relevant resolution should read :—

> "A continuous period of not less than one month in residence in hospital or conveniently nearby, attached to medical (surgical) wards."

Together with the two months' residence as obstetrical pupil, this would ensure that every student would spend four months in residence. He would thus obtain closer contact with patients, more continuous observation, and more practical experience in responsibility previous to qualification.

4. *Minor Illnesses.*—All students should obtain instruction in minor illnesses and in early stages of disease. The Committee recommend the following

resolution, which is at present the requirement of many medical schools:—

"Regular attendance in a medical (surgical) out-patient or equivalent department for a period of three months."

They also recommend the following resolution in surgery:—

"Practical instruction in minor operative surgery on the living."

5. and 6. *Systematic Lectures and Methods of Clinical Teaching.*—The Committee formulate no definite resolutions on these subjects, leaving such matters to the discretion of the individual schools.

SUBJECTS IN THE PERIOD OF CLINICAL STUDIES

The Committee make the following recommendations under:—

1. MEDICINE

Clinical Clerkship.—It is recommended that the resolution should be altered to read: "A medical clinical clerkship in the hospital wards for a period of six months."

Disease in Infancy and Childhood.—The Committee accept the view that every student should have practical acquaintance with this subject, and recommend as a resolution: "A clinical clerkship for a period of not less than one month in a children's ward or hospital." It is found that the time can be provided without interference with other duties in the six months allotted to midwifery, infant hygiene, and diseases of women.

Methods of Treatment.—Knowledge of certain methods of treatment which are not included in the present resolutions is essential, and the Committee recommend the addition of the following resolution: "Instruction in methods of treatment, including (*a*) dietetics; (*b*) therapeutics and prescribing; (*c*) physiotherapy; (*d*) principles of nursing."

Special Subjects.—The Committee have carefully considered the criticisms of the teaching of those branches of medicine which are commonly referred to as Special Subjects, and they agree that such teaching is sometimes unnecessarily detailed. At the same time it is essential that students should be reasonably familiar with the principles of these branches. They recommend that the important subject of (1) child welfare should be added to those at present required, and they further recommend the addition of (2) psychology, and (3) radiology in its application to medicine.

The Committee recommend that the following should be added to the resolutions in this section: "The instruction in these branches of medicine should be directed to the attainment of such knowledge as to ensure familiarity with common conditions, their recognition and treatment, and the indications for consultation."

2. SURGERY

Clinical Dressership.—It is recommended that the resolution should be altered to "A surgical dressership in the hospital wards for a period of six months."

The Committee agree with the opinion that students during the period of dressership spend time unprofitably in the operating theatre. They recommend the addition of the following words as a note on the foregoing resolution: "During his period of surgical dressership a student should spend the greater part of his time at the bedside and in the out-patient department; and he should not be required to attend in the operating theatre unnecessarily."

Practical Instruction in Surgical Methods.—The Committee recommend that "physiotherapy" be substituted for "mechanotherapeutics" in this resolution.

They also recommend that resolutions should be adopted in surgery, as in medicine, with reference to a period of residence in hospital, a period of instruction in the out-patient department, and the teaching of special subjects.

To the special branches of surgery they recommend the addition of "disease in infancy and childhood," "radiology in its application to surgery," and "dental diseases."

3. MIDWIFERY, INFANT HYGIENE, AND DISEASES OF WOMEN

This section of the Resolutions has recently been carefully revised by the Council. Criticisms are in the main favourable, and the Committee consider that, apart from the insertion of provision for instruction in postnatal as well as antenatal care, only minor alterations are necessary.

4. PATHOLOGY

Advances in pathology have brought it continuously into closer touch with clinical medicine. The Committee are of opinion that this aspect should be more strongly emphasised than in the present resolutions.

They recommend that the resolution should be as follows: "Pathology and bacteriology. Courses of instruction throughout the period of clinical studies in (1) general and special pathology and morbid anatomy; (2) clinical and chemical pathology; (3) general and clinical bacteriology and immunology."

The Committee have given careful consideration to the question of attendance at autopsies. It has been suggested that a certain number of attendances should be required at the commencement of the Clinical Period, and a further number towards its termination, but the Committee consider that it would be difficult for some medical schools to comply with such a requirement. Further, they are of opinion that students attend many autopsies in addition to those officially required. Consequently the Committee do not recommend alteration of the present requirement.

5. PHARMACOLOGY

The Committee recommend that the present resolution should be altered to read: "A course in pharmacology and materia medica, including practical pharmacy."

RESIDENT HOSPITAL APPOINTMENTS

The methods suggested for providing the necessary time fall into two main categories:—

(*a*) That the period should be subsequent to the completion of the five years' curriculum. The Council have no power to make any requirements subsequent to the passing of the final, or qualifying, examinations. Further, the Committee are of opinion that there are no substantial grounds for lengthening the present period before a student can become a fully qualified registrable medical practitioner.

(*b*) That a period of six to nine months in the final clinical year should be allotted to such appointments. The Committee are of opinion that no such time is available within the five years' curriculum. The appropriation of several months for such a purpose would seriously diminish the period now regarded as a minimum for fulfilling the present requirements of the Council.

If the proposed resolutions are accepted, every student will spend four months in residence in hospital and the Committee believe that this will provide the student with valuable experience of the character desired.

ADDITIONAL RESOLUTIONS

The Committee have considered the criticisms that the present resolutions contain no reference to instruction in the measures by which normal health may be maintained. They recommend that the substance of the present additional resolution (*a*) be incorporated in the body of the Resolutions, under the general heading "Medical Curriculum," by the insertion of the following paragraph:—

"Throughout the whole period of study the attention of the student should be directed by his teachers (*a*) to the importance of the measures by which Normal Health may be maintained, and (*b*) to the principles and practice of the Prevention of Disease."

INSTRUCTION IN LEGAL AND ETHICAL SUBJECTS

The Committee recommend with regard to this that instruction should be given during the later stages of the period of Clinical Studies by some person having practical knowledge of ethics, and of the statutory obligations of registered medical practitioners under the National Health Insurance Act and other Acts of Parliament.

In this instruction attention should be called to all Notices of these subjects issued by the General Medical Council.

The Resolutions

The following are the resolutions, which commence with the statement that every medical student should, at the beginning of his studies, be registered in the Medical Students' Register as prescribed by the Council.

I.—Pre-registration Examinations

Before registration as a student or commencement of the medical curriculum proper every person shall be required to pass, in addition to an approved preliminary examination in general education, an examination or examinations conducted or recognised by one of the licensing bodies, and comprising the following subjects :—

1. *Physics* (theoretical and practical), the elementary mechanics of solids and fluids, the elements of heat, light, sound, electricity, and magnetism.
2. *Chemistry* (theoretical and practical), the elementary principles of the chemical combination of elements including carbon.
3. One or two subjects of *general education* at an approved standard.

II.—Medical Curriculum

With regard to the course of study and examinations which persons desirous of qualifying for the medical profession shall go through in order that they may become possessed of the knowledge and skill requisite for the efficient practice of medicine, surgery, and midwifery, the Council recommend as follows, viz. :—

The period of professional study, between the date of registration as a medical student and the date of the final examination for any diploma which entitles its holder to be registered under the Medical Acts, should be a period of certified study during not less than five academic years.

The first two years should be devoted to the study of Professional Scientific Subjects with an introduction to Clinical Subjects. The last three years should be devoted to the study of the Clinical Subjects, together with the clinical application of the Professional Scientific Subjects.

Throughout the whole period of study, the attention of the student should be directed by his teachers (*a*) to the importance of the measures by which normal health may be maintained; and (*b*) to the principles and practice of the prevention of disease.

In every course of professional study, and in the examinations, the following subjects should be included :—

(A) PERIOD OF STUDY OF THE PROFESSIONAL SCIENTIFIC SUBJECTS

1. *Elements of General Biology.*—A course of instruction, including practical work, in the fundamental facts of vegetable and animal structure, life-history and function; and an introduction to the study of embryology. This course may commence in the pre-registration period.

2. *Human Anatomy and Human Physiology.*—These courses should include :—

(1) Dissection of the entire cadaver;
(2) Anatomy of the living body;
(3) Elements of human embryology;
(4) Histology, cytology, and the principles of genetics;
(5) The principles of general physiology, the chemistry and physics of bodily functions studied as far as possible in the human subject;
(6) Elements of normal psychology.

Instruction, illustrative of that given in anatomy and physiology and introductory to later studies, should be given in the second year in the following subjects, the amount of time to be allotted to them not to exceed one-third of the total time available in that year :—

3. *Elements of the Methods of Clinical Examination*, including physical signs, the use of the stethoscope, ophthalmoscope, &c., and the examination of body fluids (with demonstrations on living subjects, normal and abnormal).

4 *An Introduction to General Pathology and Bacteriology.*

5. *An Introduction to Pharmacology.*

Note.—It is recommended that students should not pass to the Period of Clinical Studies until they have satisfied the examiners in the subjects of the first and second years.

(B) PERIOD OF CLINICAL STUDIES

This period occupies the third, fourth, and fifth years of the medical curriculum proper. These should be calendar years, during which clinical instruction should be continuous. A minimum period of three years should in every case be given to clinical study in an approved hospital after the completion by the student of the professional examinations held at the close of the second year of the medical curriculum proper.

6. *Medicine*, including :—

(1) Systematic instruction in the principles and practice of medicine;
(2) A medical clinical clerkship in the hospital wards for a period of six months;
(3) A continuous period of not less than one month in residence in hospital or conveniently nearby, attached to medical wards;
(4) A clinical clerkship for a period of not less than one month in a children's ward or hospital;
(5) Regular attendance in a medical out-patient or equivalent department for a period of three months;
(6) Regular instruction and demonstrations in applied anatomy and physiology during the period of clinical studies, to be carried out by the teachers of anatomy and physiology and the clinical teachers jointly;
(7) Instruction in methods of treatment, including (*a*) dietetics, (*b*) therapeutics and prescribing, (*c*) physiotherapy, (*d*) principles of nursing;
(8) Instruction in the following branches of medicine: (*a*) disease in infancy and childhood, and child welfare, (*b*) acute infectious diseases, (*c*) tuberculosis, (*d*) psychology and mental diseases, (*e*) diseases of the skin, (*f*) radiology in its application to medicine, (*g*) theory and practice of vaccination.

Note.—The instruction in these branches of medicine should be directed to the attainment of such knowledge as to ensure familiarity with common conditions, their recognition and treatment, and the indications for consultation.

7. *Surgery*, including :—

(1) Systematic instruction in the principles and practice of surgery;
(2) A surgical dressership in the hospital wards for a period of six months;

Note.—During his period of surgical dressership a student should spend the greater part of his time at the bedside and in the out-patient department; and he should not be required to attend in the operating theatre unnecessarily.

(3) A continuous period of not less than one month in residence in hospital or conveniently nearby, attached to surgical wards;
(4) Regular attendance in a surgical out-patient or equivalent department for a period of three months;
(5) Practical instruction in surgical methods, including physiotherapy;
(6) Practical instruction in minor operative surgery on the living;

(7) Instruction in the administration of anæsthetics, the candidate being certified to have administered anæsthetics on at least ten occasions;

(8) A course of instruction in operative surgery;

(9) Regular instruction and demonstrations in applied anatomy and physiology during the period of clinical studies, to be carried out by the teachers of anatomy and physiology and the clinical teachers jointly;

(10) Instruction in the following branches of surgery: (*a*) disease in infancy and childhood, (*b*) diseases of the eye and principles of refraction, (*c*) diseases of the ear, nose, and throat, (*d*) radiology in its application to surgery, (*e*) venereal diseases, (*f*) orthopædics, (*g*) dental diseases.

Note.—The instruction in these branches of surgery should be directed to the attainment of such knowledge as to ensure familiarity with common conditions, their recognition and treatment, and the indications for consultation.

8. *Midwifery, Infant Hygiene, and Diseases of Women*, including:—

(1) Systematic instruction in the principles and practice of midwifery and gynæcology, including the applied anatomy and physiology of pregnancy and labour.

(2) Lectures and demonstrations in clinical midwifery, infant hygiene and gynæcology, and attendance on the practice of a maternity hospital or of the maternity ward of a general hospital, and on in-patient and out-patient gynæcological practice, for a period of six months, this period to be subsequent to the medical clinical clerkship (paragraph 6 (2)) and the surgical dressership (paragraph 7 (2)). During this period the hours of clinical instruction should be so allotted that at least two-thirds are given to midwifery, including antenatal care and the hygiene of infants.

(3) Of this period of clinical instruction not less than two months should be spent as a resident pupil either in a maternity hospital, or in a hostel attached to a maternity hospital or the maternity wards of a general hospital, and these two months should be devoted exclusively to instruction in midwifery and in the hygiene of infants. The student should during these two months attend at least 20 cases of labour under adequate supervision.

(4) Throughout the six months the student should receive practical instruction in the wards and out-patient department of the maternity hospital in the principles of (*a*) antenatal and postnatal care, (*b*) the management of the puerperium, (*c*) the care of the new-born infant.

A certificate of having attended 20 cases of labour should be signed by a responsible medical officer on the staff of the hospital, and should state: (i) that the student has personally attended each case during the course of labour, making the necessary abdominal and other examinations under the supervision of the certifying officer, who should describe his official position; (ii) that the first five at least of the 20 cases were delivered by the student in the lying-in hospital or ward: (iii) that satisfactory written histories of the cases attended, including when possible antenatal and postnatal observations, were presented by the student and initialed by the supervising officer.

9. *Pathology and Bacteriology.*—Courses of instruction throughout the Period of Clinical Studies in (1) general and special pathology and morbid anatomy; (2) clinical and chemical pathology; (3) general and clinical bacteriology and immunology.

Each student should be required to have received practical instruction in the conduct of autopsies, and to have acted as a post-mortem clerk in at least ten cases.

10. A course in *Pharmacology and Materia Medica*, including practical pharmacy.

11. *Hygiene and Public Health.*—Instruction in these subjects should be given during the later stages of the Period of Clinical Studies.

12. *Forensic Medicine.*—Instruction in this subject and its application to practice should be given during the later stages of the Period of Clinical Studies.

13. *Legal and Ethical Obligations of Registered Medical Practitioners.*—Instruction should be given during the later stages of the Period of Clinical Studies, by some person having practical knowledge of the subject, on the statutory obligations of registered medical practitioners under the National Health Insurance Acts and other Acts of Parliament, and on the principles of medical ethics. Attention should be called to all Notices on these subjects issued by the General Medical Council.

MEDICINE AND THE LAW

Professional Secrecy where Criminal Abortion is Suspected

WHERE a woman dies as the result of an illegal operation, there is sometimes a suggestion by the police that the medical practitioners who attended her before death have improperly failed to reveal, or to extract, information which would have led to the abortionist's prosecution. Naturally there is no certainty that a dying woman will always have told the doctor the name of the person who performed the illegal operation; but the point is made that, if no such statement is taken from her, no person is identified against whom proceedings can be taken. Such a case occurred at an inquest last week. It is one of those which show the difference between police or magistrates and doctors in their approach to the problem. The doctor is primarily concerned to save life and alleviate pain, and for this purpose will not destroy the patient's confidence and peace of mind by persistent cross-examination; the forces of law and order do not want a criminal to go unpunished. The situation is by no means novel. The dilemma was brought to notice in a well-known instance in 1914 by Mr. Justice Avory in addressing the grand jury at Birmingham assizes (THE LANCET, 1915, i., 28). On that occasion three doctors had attended the dying woman; to one of them she had mentioned the abortionist's name; among her papers was a letter apparently making an appointment with the abortionist. That was all the evidence against the accused, if evidence it could be called, and the case could not proceed. The Royal College of Physicians of London, which had stated a case earlier for the opinion of Sir Edward Clarke and Mr. Avory (as he then was), took up the matter again and published (ibid., 1916, i., 313, and 1932, ii., 847–915) its own view of the medical practitioner's duty. It upheld the essential confidentiality of the relationship between doctor and patient, but added that every doctor who is convinced that criminal abortion has been practised on his patient should urge her, especially when she is likely to die, to make a statement which may be used against the person who performed the operation "provided always that her chances of recovery are not thereby prejudiced." The Royal College went on to say that, in the event of her refusal to make such a statement, the doctor is under no legal obligation to take further action but should continue to attend the patient to the best of his ability; if the patient dies, the doctor will refuse to give a certificate of death and will communicate with the coroner. The College was advised by counsel that legally the doctor is under no obligation either to urge the patient to make a statement or, if she refuses, to take any further action. While this view of the legal position may not obtain the concurrence of chief constables or of magistrates and judges, it is a reasonably safe guide for the medical practitioner as to his professional duty. If the patient is dangerously ill, a magistrate may take a voluntary statement from her on oath or affirmation which will be available in criminal proceedings after her death, provided that the accused person had reasonable notice and opportunity of being present and cross-examining. A "dying declaration," made by the patient in the belief that her end is approaching, may be made verbally to the medical practitioner or anybody else and will be admissible in evidence. The recipient should write down the exact words used as accurately and as early as possible.

Accessories to Crime

A more active kind of intervention between police and criminals has lately been discussed in America. Dillinger and other public enemies, it appears, may have sought the professional aid of doctor or surgeon in order to disguise the tell-tale impressions left by their finger-prints. The practitioner who undertakes such work can hardly be ignorant of its criminal purpose. He is likely to be prosecuted as an accessory after the fact if, knowing a felony to have been committed, he receives, relieves, comforts, or assists the felon. To "receive" a felon covers "any assistance whatever given to one known to be a felon in order to hinder his being apprehended or tried." This is so stated in Hankins's Pleas of the Crown in a passage quoted with approval in R. *v.* Levy in 1912. The accused in that case had helped a coiner by removing fragments of coining moulds from the coiner's room with the idea of preventing them from being evidence against the coiner. To help a criminal to prevent his known finger-prints from being impressed is clearly to attempt to hinder his being apprehended. If a doctor helps a known "public enemy" in this way, then, apart from the prospect of his criminal liability as an accessory before or after the fact, he might possibly be indicted under the vague and comprehensive accusation, lately discussed in R. *v.* Manley, of doing an act which is a public mischief.

Prisoners Absconding from Hospitals

George Rivers, aged 36, serving a sentence in Wandsworth Prison, was sent to the St. James's Hospital, Wandsworth, for an operation. Though he was described as a dying man who, with the best possible treatment, might live another month, he managed to escape from the hospital on May 26th after scaling a 7 ft. wall. Wearing his blue hospital suit at his departure, he remained at large until he gave himself up last week at the prison. Such incidents are a reminder that civil hospitals are not equipped for the restraint of patients sent from prison. The latest statistics available show that 109 male and 18 female prisoners were removed from prisons to civil hospitals for operation or special treatment during 1933. The statutory authority is Section 17 (b) of the Criminal Justice Administration Act of 1914, which declares that, while absent from prison in this way under Home Office order, the prisoner is still deemed to be in legal custody. The Prisons Commissioners' report for 1933 contained a statement by the Medical Commissioner that on the whole the prisoners conducted themselves well, "but a few abscond and some hospital authorities are apprehensive when a patient is admitted to a general ward from prison." The apprehension is not entirely surprising and the report explains that steps are being taken to have an operation theatre available in a prison in the London area. Experience has been gained by the satisfactory carrying out of major operations in five provincial prisons.

AUSTRALIA

(FROM OUR OWN CORRESPONDENT)

THE TREATMENT OF INFANTILE PARALYSIS

MUCH controversy in which the main issues have been clouded by spirited attack and counter attack in the public press has arisen during the last few months about the merits of a certain method of treating established infantile paralysis. The story began in February last when it was announced in the public press of Australia that a new system of treating infantile paralysis had been presented to the Commonwealth Government, which in the opinion of prominent medical men had achieved success not previously obtained by other methods. In the *Sydney Morning Herald* of Feb. 16th it was stated that the system had been devised by Sister Elizabeth Kenny and had been approved by the Queensland Department of Health. Dr. J. F. Guinane, who had carried out an investigation for the Queensland Government, was said to have reported that Sister Kenny's methods had made total and permanent cures in early cases of infantile paralysis and that in spastic cases it was superior to any other method. The origin of the treatment, according to this report, was the work done by Sister Kenny during the war when nursing cases of meningitis on troop-ships; during that period she is said to have evolved certain ideas on the treatment of paralysis, and after the war she began to apply these ideas in the treatment of victims of infantile paralysis and cases of spastic paralysis. Sir Raphael Cilento, Director of Medical Services in Queensland, had, it was said, been deputed to investigate the matter, and had reported so favourably that the Government of Queensland had opened a clinic in Townsville in March, 1934, to train students in the methods.

A silent film was shown to medical men and others, to which Sister Kenny supplied a running commentary, in which were shown the results in a number of patients treated by her methods. Three weeks later there appeared in the *Sydney Morning Herald* of March 9th the report of an interview with Sir Raphael Cilento, in which he was alleged to have said: "The Queensland Government or myself do not approve or disapprove of Sister Kenny's method." He had investigated her method and acting on his report the Government had opened a clinic at Townsville in March, 1934. The clinic with a staff of six nurses was established for a two-year period from funds provided by the Home Department. His report was to the effect that her treatment had improved the health of patients particularly in regard to their general activity. In no case had she restored the functions that had been lost by nerve destruction.

The next step in the matter came on March 14th from Canberra where Sister Kenny had gone to place her proposals before the Commonwealth Government; she expressed her astonishment at Sir Raphael Cilento's statements and produced a letter dated Jan. 31st in which, she said, Sir Raphael mentioned his agreement to write a book descriptive of her methods. In his reply to this, in the *Brisbane Courier-Mail* of March 15th, Sir Raphael said that he saw no cause to alter the opinion expressed in his official report. He had agreed to assist Sister Kenny in the compilation of a book, if and when the method should show itself effective to a degree that justified a book. Of the 16 original cases, for the study of which the Townsville clinic has been instituted, in his opinion 7 were stationary, while 5 had abandoned treatment. These were the only cases of this series which had been under observation long enough to justify even a tentative opinion.

As a result of the publicity there arose a demand from parents having children suffering from infantile and other forms of paralysis to be able to obtain the treatment. Townsville is situated in the north of Queensland and many miles from the larger centres of population. As this is the only clinic available for the treatment, crippled children have been sent by train and aeroplane to Townsville and public subscriptions have been organised in country towns to send children there. A demand also arose for the creation of clinics at Brisbane and other capital cities.

On April 2nd the Commonwealth Government announced the result of its investigations and the Federal Minister for Health and Repatriation (Mr. William Hughes) read a report which had been made to him by the medical superintendent of the Frankston Orthopædic Hospital, Victoria (Dr. Galbraith), and a Melbourne orthopædic surgeon, Mr. Whittaker, on an inquiry they had made into the treatment. Their report was as follows:—

> "It is our opinion that the only way of demonstrating the value of Sister Kenny's work, and of comparing it with orthodox methods, would be to give her facilities to treat cases, both recent and chronic, in one, or preferably two, capital cities. Such work should be carried out by Sister Kenny in person, or by her trainees. It would be wise, and with this Sister Kenny agrees, that the location of such facilities be at a public hospital, and preferably a children's hospital. Sister Kenny has always worked with the medical profession, and it is hoped that a cleavage will not be enforced by establishing clinics apart from such hospitals. Under the Hospitals Commission certain safeguards would be necessary, but we are definitely of the opinion that if the Government requests the committees of management of the hospitals to provide such facilities, some mutually satisfactory arrangement could be reached."

As the result of this report, it was decided that the Commonwealth Government should take steps to have the method tested in public hospitals in Melbourne and Sydney with the coöperation of the Victorian and New South Wales Governments. On April 11th the New South Wales Minister for Health announced that his Government had been approached by the Commonwealth Government and was anxious to provide Sister Kenny with all facilities to make an early start with her treatment. Later it was announced that it was proposed to open a clinic at the Royal North Shore Hospital, Sydney.

On May 13th it became apparent that an open break had occurred between Sister Kenny and the Queensland Government over the establishment of the Brisbane clinic. She announced that she did not intend to comply with the request by the Home Secretary to conduct a clinic in Brisbane while any doubt of the efficiency of her method existed, and that she had been unable to arrange for a clinic to be established under conditions satisfactory to her or the patients. Sir Raphael Cilento, she contended, had attempted in his report to the Home Secretary to discredit her methods, had raised doubts about its originality, and had inferred a similarity between her methods and those published by Dr. Wilhelmina Wright in the United States in 1927. (Actually Sir Raphael's conclusion had been that her work was soundly based, was effective within certain limits, and was similar in general principles to those advocated by most modern doctors and specialists.) Everyone, she added, would appreciate her unwillingness to have her work extended in Queensland in view of the unsympathetic attitude of the Government medical adviser.

The Queensland Government announced that it intended to proceed with the clinic, and on May 25th Sister Kenny in the *Brisbane Courier-Mail* stated that she had not given her permission for the use of her methods at this clinic, one reason being that the description of her method had not been officially presented to the Home Secretary. The only copy of the description of her method was in her possession. Sir Raphael Cilento had possession of an incomplete and discarded draft copy, in which one essential feature was not mentioned. She had asked the Home Secretary, in the interests of the public, to have that copy destroyed. She resented, she said, Sir Raphael's half-hearted approval of her work and his implication that her method was not original. She proposed that a committee be appointed to determine the originality of her work. Years before she had visited America she had effected cures in Australia.

A reply to this was made by Sir Raphael Cilento in which he said that the Government intended to open the Brisbane clinic and place in charge of it the nurse who was first appointed and longest trained at the Townsville clinic. He regretted that he had been made "the villain of the piece" and suggested that the real reason for her not opening the Brisbane clinic was that she had received a better offer to establish a larger clinic in Sydney. He repeated his opinion "that her work was soundly based and was effective within certain limits. To suggest that there should be no qualifications as to the effectiveness of her method was to suggest that it should be described as miraculous."

The Government also announced that it intended to make a register of all sufferers from infantile paralysis in Queensland. An effort would be made to trace every possible case and in view of the success that had attended the work so far, the Government was of the opinion that every paralysis sufferer should be given a course of after-treatment at clinics which would be established at various centres throughout the State. It was also announced that the Government had taken over the control of the Townsville clinic as a Government activity. Resentment at this action by the Government has been expressed at a meeting of the parents of patients at the clinic and a public meeting of protest is being arranged.

Sister Kenny on May 17th made a further announcement. Her attitude throughout had been that she would not extend the work at Townsville to any other centre unless she had the complete confidence of the people and Governments concerned. So that there would be no repetition of the trouble which had occurred in Brisbane, she must have an assurance, before she would accept the invitation to establish a clinic in Sydney, that the authorities in New South Wales were convinced of the originality of her method, its scientific basis, and its value to the medical profession. For this purpose a Sydney doctor would visit her in Brisbane within a week, and when the Queensland Government was prepared to comply with her conditions for the protection of all concerned, she was ready to serve the people of that State.

The medical profession in Australia and the public generally are very much in the dark concerning the whole matter, and no public disclosure of the method has been made. The first announcement was somewhat modified by the medical authorities in Queensland, who state that the results obtained have been satisfactory, but discount anything miraculous. On the other hand, a letter has appeared in the

Courier-Mail, May 14th, signed by five of Sister Kenny's patients, in which they state that all but one of them had had many years' experience with orthodox methods of treatment, and that results were obtained by Sister Kenny's methods which appeared impossible of accomplishment by the ordinary treatment; the improvements had been of a permanent nature and no relapse had occurred in five months.

What the exact nature of the treatment consists in is difficult to ascertain. Undoubtedly re-education plays a large part in it. By some the treatment is regarded as being of the nature of psychic cure by a woman of outstanding personality. It is considered that her personal service and supervision in carrying out the treatment plays a large part in its success. The method is reputed to differ from those ordinarily adopted in the following respects:—

1. No splinting or plaster is used at any stage of treatment.
2. Movements are carried out where possible under water, to which some salt is added.
3. Treatments are given frequently during the day, with rest periods between.
4. Hydrotherapy in the form of sprays and showers is used.
5. Attempts at active and passive movements are made at the earliest possible moment.

As Sister Kenny has nowhere set out the details of her method, there is no way of checking these impressions which are based on reports and on remarks made by her whilst demonstrating her film.

In view of the public interest in this matter, it is to be hoped that a public disclosure of the method will soon be made. Amongst medical men who have examined patients treated by the method, there appears to be considerable divergence of opinion as to its value.

AN UNUSUAL MEDICO-LEGAL PROBLEM

About the middle of April some fishermen caught a large tiger shark on the Coogee Beach for the purposes of exhibition at the Coogee Aquarium. The shark refused to eat and for a week swam lazily up and down the pool, brushing its body against the sides. On April 25th it began to flay the water to foam, dashed up to one end of the aquarium, and threshing wildly with its tail, disgorged several objects. These included some vertebræ of a large fish and a human arm. A piece of rope was tied tightly around the wrist and the arm was in a good state of preservation. There was a large gash in the front of the arm just above the elbow and some small irregular and superficial incisions, which may have been caused by the teeth of the shark, on the back of the forearm. The arm was cleanly cut through just beyond the acromion and cleanly dissected off at the shoulder-joint. On close examination it was thought by the authorities to be unlikely that a bite of a shark could have so nearly removed the arm through the joint, and that removal was probably by human agency. It was clear from the flaps that the method adopted was not surgical, and the arm showed no evidence of being a discarded dissecting-room specimen. On the front of the forearm was a tattoo mark of two men boxing. The police continued their investigations; they obtained the fingerprints with some difficulty and later the arm was identified by its tattoo marks and fingerprints as belonging to a man who had disappeared from his home on April 8th and had since then not been heard of. As nobody was forthcoming, the city coroner could hold no inquest and there was not sufficient of the body to permit him to hold a magisterial inquiry. It is thought that the police will attempt to overcome their difficulty by bringing medical evidence to certify that the owner of the arm could not have lived without medical attention. A man has been arrested and charged with murder. The incident is not altogether without precedent, as according to a story in H. S. Mazet's book "Shark! Shark!" the crew of the brig *Nancy* were sentenced for piracy in 1771 on the evidence of a log book found in the stomach of a shark.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

NEUROPATHOLOGY

THE Scottish mental hospitals have a joint scheme for pathological research, and an account of its thirty-seventh year's work has just appeared. Two years ago the board secured the services of Dr. J. H. Biggart as pathologist, and he has been able to form a highly efficient laboratory for the study of neuropathology. Specimens are sent to him from many of the mental hospitals in Scotland, and from general hospitals in Edinburgh, particularly the Royal Infirmary where the laboratory is situated. His services are already much appreciated by all who are interested in neuropathology, and it is to be hoped that his laboratory will be increasingly used both for routine examination and for research work. A specialised laboratory such as this is essential for the proper study of the pathology of the nervous system, owing to the complicated nature of the modern staining technique.

A CHILDREN'S HOSPITAL

The annual report of the Royal Edinburgh Hospital for Sick Children shows that its work is steadily increasing. A total of 3144 cases were treated in the wards during the year, and the number of attendances at the out-patient department, including the massage and sunlight departments, was nearly 40,000. The ordinary income amounted to £14,264; the income from legacies and the like was £10,280; and the expenditure for the year was £19,019. During the year 190 patients were treated in the convalescent home at Gullane. Through the generosity of Lord Forteviot and members of the Dewar family a new convalescent home for children under two years of age is to be opened. The medical staff intend to start a campaign against rheumatism in childhood, which they compare to cancer in the adult. No disease is more tragic and they are to be congratulated on this intention.

PIONEERS IN MENTAL DISEASE

Bronze plaques in memory of six pioneers in the humane treatment of mental disease were unveiled last week by Sir Arthur Rose, chairman of the General Board of Control for Scotland, in the grounds of West House, Royal Edinburgh Hospital for Mental and Nervous Disorders. They are arranged around the bust of Philippe Pinel, and commemorate the work of William Tuke, Andrew Duncan, Florence Nightingale, Dorothea Dix, Gardiner Hill, and Campbell Clark. Tuke was the founder of the Retreat in York, and Duncan of the Royal Edinburgh Asylum. Dorothea Dix, an American, after visiting the asylum, was so impressed by the work done there, that she made a report which resulted in the Lunacy Act of 1857 coming into being. Gardiner Hill had much to do with the abolition of restraint and locking-up in mental cases; Florence Nightingale had advanced ideas in practice and theory on the treatment of mental cases; and Campbell Clark advocated the registration of nurses both male and female. The leading part played by the Royal Edinburgh Hospital in the treatment of mental diseases was emphasised by speakers at the ceremony, and it was pointed out that the hospital was the first to use women nurses for the care of the mentally afflicted. This has proved to be one of the biggest advances made in the treatment of mental disease.

PARIS

(FROM OUR OWN CORRESPONDENT)

PROFESSIONAL DISCIPLINE

I HAVE already referred to the proposal to create a doctor's Order which, modelled to some extent on the one that governs the legal profession, should fulfil certain functions of the English General Medical Council. Matters have now advanced so far that the Bill in question has passed the chamber of deputies without discussion and has come back again after a certain amount of mutilation by the Senate. It remains to be seen whether the chamber will approve of the modifications now made. One of them concerns the composition of the final court of appeal; the Confederation of Medical Syndicates would have liked this court to consist of two lawyers and four doctors, but the senate prefers three doctors and three lawyers. As the president would be one of the legal experts and would have a casting vote, the balance of power would be with the layman. This point may be trivial or crucial. On the whole it is thought to be trivial for experience elsewhere has shown that the legal mind will often defer to the opinion of the medical profession in its own realm. In other words, legal acumen is not always divorced from common sense.

Meanwhile, it is interesting to note that the need for a doctors' Order was almost met as long ago as 1845, when a scheme was on foot for the creation of "medical colleges" with functions mainly disciplinary. Like much other useful legislation this scheme came to nothing in the revolution of 1848; and its suspension was regarded on the whole with equanimity by the doctors of that day, who saw in it rather too much of the schoolmaster. This was a time when the ethical standard of the medical profession was jealously kept at a high level. The black sheep was comparatively conspicuous, partly because the fold was small, partly because he was obviously in the minority. Now, it is regretfully admitted, the fold is far larger than the remunerative pasturage, and the many genuinely black sheep are the less conspicuous because there are so many piebald cross-breeds in the flock. Much of the blame for the lowering of standards is laid at the door of sickness insurance, which has created new conditions of medical practice. These conditions certainly afford wonderful opportunities for smartness and a nimbleness of wit which is sometimes construed unfavourably by colleagues who are not so agile mentally. It remains to be seen how the new Order will deal with these problems. Its enemies gleefully point to the not infrequent lapses of which lawyers are convicted despite the disciplinary terrors of their Order.

USE OF BARBITURATES FOR SUICIDE

The vogue of barbiturate suicides has now become so embarrassing that the minister of public health has asked the Academy of Medicine to give an opinion on the desirability of including certain barbiturates and other drugs among those which cannot be bought without the signature of a doctor. The Société de Pharmacie de Paris recently adopted a unanimous resolution recommending, among other things, the examination of this problem by a commission which might well be the Commission Permanente du Codex. Hitherto legislation and practice have wobbled uncomfortably from one extreme to the other. There have been times when you could not buy syrup of tolu without a doctor's prescription, whereas at present you can buy without prescription all you need and more to secure your early demise. As for the barbiturates, whose usefulness in insomnia is unquestionable, the suggestion has been made that they be combined with ipecacuanha in proportions assuring the speedy return of the drug taken in suicidal doses; indeed, a formula for the purpose is said to have been devised already. It is to be hoped that this expulsive compromise will be adopted, for the public is so accustomed to the purchase of certain popular hypnotics that it would assuredly resent the imposition of medical restrictions at this time of day. After all, poisoning by the barbiturates is fairly easily dealt with in hospital provided the case is not exceptionally severe. From the Saint-Louis Hospital Dr. C. Flandin reports encouraging experiences, in more than 200 cases, with injections of strychnine. He prefers it to Coramine or anything else as an antidote; but the dosage must not be *timid*. He has never known strychnine kill the patient offhand, even when 50 mg. (gr. ¾) was given intravenously. The dosage he recommends, under the control of Chovstek's sign, is between 20 and 50 mg. repeated every half-hour or hour till the desired effect has been obtained. He reinforces this treatment by venesection, blood transfusion, and, above all, by artificial respiration supplemented by the inhalation of a mixture of oxygen and CO_2. Adrenalised serum, given per rectum, is also useful. If too much strychnine has been given, there are antidotes to it; Gardenal is too toxic for this purpose, but Isonal gives a much wider margin of safety. Dr. Flandin dispenses with alcohol, for he is inclined to regard it as an adjuvant rather than as an antidote to barbiturate poisoning.

THE INTERNATIONAL UNION AGAINST CANCER

After a difficult labour lasting more than ten years, the International Union against Cancer was born on May 4th of this year. Forty-four nations were represented on this occasion. Justin Godart is the first president of the Union, whose headquarters will be in Paris. In his presidental address he outlined the steps which led to the birth of the Union and referred briefly to its future functions.

KING GEORGE HOSPITAL, ILFORD.—For the coming year a maintenance income of approximately £40,000 will be required. There has been during the past year a capital outlay of over £21,000, and the building fund has been reduced from £24,720 to £18,950. During the year 142 beds have been available and 154 occupied, daily extra beds being constantly in use.

NOTTINGHAM GENERAL HOSPITAL.—Six single-bedded wards, ten 2-bedded wards, and two 4-bedded are to be provided in the pay-bed wing of this hospital. The maximum charge will be not more than 4 guineas a week maintenance rate. In addition there will be six single-bedded wards available for generous friends of the hospital, the charge for these being 10–12 guineas a week maintenance rate.

CORRESPONDENCE

THE INTERNATIONAL CAMPAIGN AGAINST RHEUMATISM

To the Editor of THE LANCET

SIR,—An active campaign against chronic rheumatic disease is now being prosecuted in many countries and with encouraging results. We desire to call the serious attention of your readers to the efforts of the modest organisation to which this widespread activity is largely due.

The first International Committee on Rheumatism was appointed in Paris just ten years ago.[1] A few months later (November, 1925) an International Conference on Rheumatism was held at the house of the Royal Society of Medicine, and addressed by Sir George Newman, on behalf of the Ministry of Health, and Dr. Kahlmeter, of the Board of Pensions in Sweden. Reports were presented from England, France, Holland, Denmark, Switzerland, and Rumania.

Following this conference the International League against Rheumatism was constituted as an independent body, with a central council consisting of national representatives, and began its task of associating in one organisation the isolated workers in rheumatic disease. Meetings were called and committees were quickly set up in many countries. A periodical journal, the *Acta Rheumatologica* in three languages, was produced and widely circulated, and a small central bureau and library were opened.

International congresses, arranged with the help of the national committees and attended by government representatives from the countries seriously affected by rheumatic disease, have awakened great interest in the medical profession, and in industrial and social bodies. The problems of research and treatment, together with the social, economic, and industrial results of rheumatism, have been examined at these meetings—in Prague, Budapest, Liége, Paris, and (1934) Moscow. The next Congress is due in Sweden in 1936.

Fortunately the costs of the journal have in most years been nearly met by personal subscriptions, but apart from the journal the wide activities of the League, in which there is no salaried officer, entail a certain (very moderate) expenditure. This has been until lately met by contributions from a number of national groups. Unfortunately now, owing to widespread economic difficulties, most of the countries connected with the League are unable to continue their grants. The actual income in 1934 has fallen on this account to one-third of what it was in 1931. The annual deficits (£119 for 1934 and £316 for previous years) now amount to £435, and have been met by officers and friends of the League.

The famous Report of the British Ministry of Health in 1924 on the Incidence of Chronic Rheumatic Diseases called attention to the extent and gravity of the rheumatic problem in northern countries, and this report is still regarded as a milestone wherever rheumatic diseases are being seriously studied. Britain gave this lead, and has done excellent work in following it up. It is, however, rather humiliating that while smaller nations, known to be distressed, have subscribed or, if unable to subscribe, made up deficiences from private sources, this country, which has benefited not a little by the work of the League, has not come forward with any financial support. Probably this is an accidental oversight, and we should be proud to shoulder our share of the burden.

At the last meeting of the Committee on Chronic Rheumatic Diseases appointed by the Royal College of Physicians it was resolved: "That this committee recognise the value of the work being done by the International League against Rheumatism, and consider it worthy of the support of all interested." A sum of £1000 is needed to tide over the emergency until more normal conditions are restored. We hope that this sum will be forthcoming from public bodies and private individuals who may be glad to supply this need. Contributions may be sent to A. C. Timbrell Fisher, Esq., M.C., F.R.C.S., 59, Montagu-square, W.1.—We are, Sir, yours faithfully,

R. FORTESCUE FOX,
President of the League.

ZOOLOGY AND MEDICINE

To the Editor of THE LANCET

SIR,—The profound connexion between medicine and zoology in the past and at the present time offers ample justification for a discussion on their present relations. Every medical graduate is a zoologist of a kind, a homozoologist; and every specialist on any kind of animal, vertebrate or invertebrate, is a zoologist of the same order as the human specialist. Their problems are comparable and their affinities manifest. Thus, although every zoologist does not specialise in one animal nor does every medical graduate specialise in the ensemble of man, their fundamental needs in training are, it will be generally admitted, similar to a great extent.

The precise extent of the needs of the medical student, as defined recently by the conference of representatives from Oxford, Cambridge, London, the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Society of Apothecaries of London, will doubtless be considered by the General Medical Council which, it is understood, has the same problem under consideration. If, however, the thesis that the basic training needs of zoologist and medical student are largely identical is admitted, it would seem advisable that the problem be discussed with representatives of such a body as the British zoologists. The writer holds the view that, although a good elementary knowledge of botany is important to the medical student, the zoological training is of far greater importance and needs special consideration.

In reviewing the medical curriculum as a whole it is necessary to decide whether knowledge of the following subjects, for example, is desirable and in which part of the curriculum, if any, they should be treated:—

An acquaintance with the chief groups of animals and more detailed knowledge of amœba, paramecium, hydra, obelia, lumbricus, periplaneta; along with elementary comparative anatomy of fish, amphibian and mammal.

Elementary histology of vertebrate tissues.

Elementary knowledge of the function of all parts of the body, leading to an appreciation of the functions of the body as a whole.

Elementary knowledge of common parasites—e.g., monocystis, plasmodium, entamœba, ancylostoma, distomum, bilharzia, tænia, ascaris.

Elementary knowledge of common pests—e.g., house-fly, mosquito, flea, bug, lice, sarcoptes, and poisonous animals.

Simple Mendelian characters in plants and animals including man) and simple facts of variation.

The principle of shell-fish cleansing.

Sex-phenomena and modes of sex-determination. simple facts of dedifferentiation and regeneration. tissue-culture.

Commensalism. symbiosis and parasitism.

Development and differentiation in a minimal series. as echinus. amphioxus. chick, mammal.

Argument for evolution based on simple *facts* of geological succession of vertebrates, of embryology. physiology, classification, distribution and modification of organs.

Animal behaviour. animals and their environment. and theories of evolution treated in a very elementary manner.

Elementary practical experience : in dissecting. in use of microscope, in identification of bones. of fresh and preserved tissues, of living animals and stages of life-histories.

It follows that if a knowledge of all or most of these subjects is desirable in the first year of training. the subject matter of zoology alone becomes comparable in extent with that of elementary physics and elementary chemistry.

I am. Sir. yours faithfully.

J. H. ORTON.

The University, Liverpool. June 11th.

*** The report of the Curriculum Committee of the G.M.C.. adopted by the Council as an interim document for the consideration of the training centres. was not published when Prof. Orton wrote : but his letter is very apposite when read in connexion with the Committee's recommendations.—ED. L.

STIMULANTS OF METABOLISM

To the Editor of THE LANCET

SIR.—My remarks in the annual oration of the Medical Society of London on May 13th concerning dinitrophenol and Dekrysil (4 : 6-dinitro-o-cresol) followed others on the need for caution in the use of cinchophen (Atophan). which has caused toxic jaundice in a number of cases seen by me personally. The nitrobenzene derivatives, such as trinitrotoluene, dinitrobenzene. dinitrophenol. and picric acid (trinitrophenol) have all been recognised as liver poisons and they, too. have caused numerous cases of toxic jaundice. Dinitrocresol (dekrysil) as regards its toxic action on the liver belongs to this group of drugs and it was for this reason that a note of warning was given by me.

Prof. E. C. Dodds. for whose scientific work I have a high regard. strongly emphasised in his published papers the need for great care in the therapeutic use of dekrysil and was obviously fully aware of possible dangers from over-dosage. The case quoted by Dr. Wilfrid D. Newcomb in your issue of June 1st (concerning which I was consulted) fully confirmed the dangers to the liver and kidney from over-dosage, such as would be likely to occur in a young dancer for whom the urge for slimming was great ; there was no suggestion of suicide in this case. The liver and kidney cells showed remarkable degenerative changes.

Cases of disturbing symptoms from the use of dekrysil have been brought to my notice and it appears that certain persons are highly susceptible to this drug. as is known to be the case with dinitrophenol. Prof. Dodds wisely advised that its action should be controlled by determinations of the basal metabolic rate and careful medical observation of other symptoms. This supervision. however, is only really effective in hospital or nursing-home. It is doubtful if patients suffering from obesity and carrying on their ordinary avocations can be trusted to obey implicitly the injunctions of their medical advisers as regards dosage when their weight is not falling as rapidly as they desire. It is here that the danger comes.

I am, Sir, yours faithfully,

WILLIAM H. WILLCOX.

Welbeck-street, W., June 11th.

To the Editor of THE LANCET

SIR.—Prof. Dodds and Dr. Robertson in your issue of May 25th. commenting on Sir William Willcox's reference to the use of dinitro-o-cresolin the treatment of obesity, . state that provided a careful watch is kept on the patient and the basal metabolic rate is measured frequently, there is no danger in its use. Our experience with dekrysil at Kasr-el-Aini Hospital. results of which have been published elsewhere,[1] show that the B.M.R. is not an accurate index to the toxicity of the drug. We have encountered cases which showed grave toxic symptoms (severe vomiting, giddiness. cold sweats. low temperature 35·5° C., and other features of collapse. followed later by a rise of temperature to 40° C. and then a gradual return to normal in a week's time). with a B.M.R. of ÷ 34 per cent. only, whereas in other cases. the B.M.R. has reached ÷ 77 per cent. with trivial or no toxic symptoms at all. Our impression. after a fairly extensive trial. is that dekrysil as a weight-reducer is exceedingly disappointing. and is not free from danger.—We are, Sir, yours faithfully,

MOHAMED IBRAHIM, M.D., M.R.C.P.
HOSNY AYAD, M.B.

Medical Section, Kasr-el-Aini Hospital, Cairo.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING WEEK ENDED JUNE 1ST, 1935

Notifications.—The following cases of infectious disease were notified during the week : Small-pox. 0 ; scarlet fever. 2093 ; diphtheria. 971 ; enteric fever. 32 : acute pneumonia (primary or influenzal). 1118 ; puerperal fever. 42 : puerperal pyrexia. 119 ; cerebro-spinal fever, 15 ; acute poliomyelitis. 7 : acute polio-encephalitis. 4 ; encephalitis lethargica. 3 ; dysentery. 38 : ophthalmia neonatorum. 94 ; No case of cholera. plague. or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals for the London County Council on June 7th was 2977. which included : Scarlet fever, 943 ; diphtheria. 1155 : measles. 28 ; whooping-cough, 375 ; puerperal fever, 30 mothers (plus 11 babies) ; encephalitis lethargica. 269 : poliomyelitis. 3. At St. Margaret's Hospital there were 16 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns. including London, there was no death from small-pox. 2 (0) from enteric fever. 16 (0) from measles. 7 (0) from scarlet fever. 20 (3) from whooping-cough, 33 (2) from diphtheria. 41 (15) from diarrhœa and enteritis under two years. and 58 (8) from influenza. The figures in parentheses are those for London itself.

Beckenham and Sheffield each reported one fatal case of enteric fever. Three deaths from measles occurred at Liverpool and at Wigan. Sheffield reported 4 fatal cases of diphtheria. Liverpool 3. no other great town more than 2. Of the deaths attributed to influenza 5 occurred at Bradford, 4 at Birmingham.

The number of stillbirths notified during the week was 282 (corresponding to a rate of 41 per 1000 total births.), including 40 in London.

INFANTS HOSPITAL. VINCENT-SQUARE.—The income of this hospital for the past year was £18,287 and the expenditure £18,965. The hospital now contains 100 cots and seven separate rooms for nursing mothers. The building extension scheme was completed in the autumn.

OBITUARY

WILLIAM STUART-LOW, F.R.C.S. Eng.

CONSULTING SURGEON, CENTRAL LONDON THROAT AND EAR HOSPITAL

We owe the following memoir to Sir James Dundas-Grant: "William Stuart-Low's death from heart failure following influenza was the end of a very remarkable career. He was born at Burntisland, in Fife, in 1857. His father was in the scholastic profession and doubtless bequeathed to him the capacity for teaching which displayed itself when he joined the staff of the Central London Throat and Ear Hospital. Intended for the veterinary profession, he was attracted to that of medicine and was able to qualify in 1884 as Licentiate of the Royal College of Physicians of Edinburgh. According to his own story, having his way to make, he started practice in a working-class neighbourhood in the south-western district of London, taking also a resident patient into his house to help towards the necessary expenses. He then migrated to the more desirable surroundings of *Herne Hill* where he had the good fortune to meet a lady of both personal and intellectual attractions, who became his wife. She added greatly to the brightness of his life and he afterwards spoke of her as the 'best friend he ever had.' While in busy practice he made time for preparing for the Fellowship of the Royal College of Surgeons of England, absorbing with avidity both the academic teaching and the *obiter dicta* of those from whom he sought instruction. He was particularly inspired by the teaching of the late Wm. Anderson, surgeon to St. Thomas's Hospital, for whose anatomical accuracy and surgical refinement he had the greatest admiration.

MR. STUART-LOW

"In 1903 he was appointed to the staff of the Central London Throat and Ear Hospital at the age of 46. Both there and at the Polyclinic—the Medical Graduates' College in Chenies-street, W.C.—he made his mark as a teacher and thereby added considerably to his success in consulting practice. Curiously, he was guided more by his *perfervidum ingenium* than by the Scotch tendency to rely on strict logical reasoning. It may be said that his methods were inductive rather than deductive, and he had original views which when tested in his own practice had a remarkable measure of success. His insistence, for instance, on the value of mucin in cancer of the throat may not be universally accepted, but there can be no doubt as to the relief afforded by the use of his preparations. His use of horse serum in the irrigation and dressing of operation wounds was an original idea, but it appears to have its equivalent in some modern methods of treatment. He devised a number of details in dressing, fixing, and dealing with operation cases, which afforded evidence of his originality.

"At the Royal Society of Medicine he was a very regular attendant, though he did not show many cases. His remarks, however, were at times inspired by his difference of opinion from that of some previous speaker. He then expressed himself with deliberation and emphasis, and if he appeared to be unnecessarily downright in his utterance it was probably because he had formulated in his mind what he had to say tersely and without the frills with which too many speakers embellish their statements.

"Stuart-Low was powerfully built and endowed with exceptional physical vigour. An unusually early riser, he took a pride in performing his operations when others had not yet breakfasted. In spite of his commanding figure he tended on the whole to be shy and reserved, and the sensitiveness of his disposition was known probably to only a few. He was not a prolific writer, but he put forward his views with decision and happy phraseology. His work on 'Mucous Membranes, Normal and Abnormal, including Mucin and Malignancy,' published in 1905, amply illustrates the characteristics of his vigorous modes of thought.

"To the writer he was ever a loyal friend, whether as pupil, assistant, or colleague, and he and many others with him will greatly miss Stuart-Low and deplore his decease. He is survived by his widow and a son and daughter."

J. D.-G.

PANEL AND CONTRACT PRACTICE

Study Courses at Hammersmith

We have already noted that the British Post-graduate Medical School is arranging during the coming summer intensive "refresher" courses for general practitioners. The first of these courses, of which full details will be found in our advertisement columns, opens next Monday, *June 17th, and* as only a limited number can be admitted to one course early application for the later courses is recommended. Here it is appropriate to consider the circumstances in which certain insurance practitioners may receive financial assistance towards such study. Assistance is made by way of grants from the special expenses portion of the central mileage fund, and it must be shown that the doctor (1) has been in practice other than hospital practice at least one year before the date of application; (2) practises in an isolated or sparsely populated rural area and has no reasonable access to a town in which hospital practice is available and meetings of medical societies can be attended; and (3) is unable, without assistance, to afford the cost of a course of study. Recommendations are made to the Ministry of Health not later than the end of February in each year jointly by the insurance committee and the panel committee which must satisfy themselves that applicants fall within the terms of eligibility. Applications for a further course would be entertained after an interval of five years, unless special reasons are advanced for a repeat course at a shorter interval. The available fund is limited, and applications from any area are considered in relation to those from the country as a whole. Normally the grant would not exceed £20, but in exceptional cases the whole cost may be met (subject to prescribed maxima under each item) for subsistence expenses, travelling expenses to the nearest suitable centre, course fees, and the engagement where required of a whole-time locum tenens.

It should be borne in mind that the scheme is restricted to insurance practitioners in rural districts, and it is, presumably, now too late to apply for assistance for the year 1935, although in view of the new situation created by the opening of the Hammersmith school it might be well to test this.

Refusal to Visit: Charge Rebutted

A London insurance practitioner was recently charged with having failed to visit a patient on request. The complaint was that the woman having been discharged from hospital became ill the same evening and requested a home visit on the following morning, but the practitioner declined to come and the services of another doctor were obtained.

The practitioner pointed out that he had received a telephone message from the house physician to one of the honorary staff of the hospital to the effect that the patient had discharged herself voluntarily, that she had been in bed for two weeks, had been examined by the "honorary" personally, had had numerous X rays taken, and every conceivable pathological test, all with negative result. The hospital authorities had told her, she was not ill but had advised her to remain a day longer to get used to being out of bed. The practitioner having attended her at home or at his surgery 43 times during the previous 12 months without ever finding any sign of physical disease agreed with the opinion of the house physician that while there might be a neurotic element in the patient's condition she was not physically ill. Next morning he received a clinical report from the hospital and soon afterwards a message from the patient's mother asking for a home visit. Being engaged with another patient he sent a message to the mother that he had been informed by the hospital that her daughter was not ill, but if she wished to see him she could come to the surgery—less than two minutes' walk. The mother sent a further message that the patient was ill and needed attention, to which he replied that he was engaged but would be prepared to see the mother in half an hour's time. No further application was made for his services.

Unfortunately the patient was ill this time. The other doctor who was called in found her suffering from a febrile attack with pain in her back, vomiting, headache and general malaise, and unfit in his opinion to leave the house. Although (in the words of the subcommittee's report) she "gave a lengthy history of various illnesses from which she had suffered in the past," it might well have been held that the practitioner had committed a breach of Section 9 (5) of the terms of service in failing to visit a patient whose condition so required, but the committee took the view that the previous history of the case, coupled with the message from the hospital and the clinical report, doubtless prompted the practitioner to regard as unreasonable the request for a home visit within 24 hours after the patient had voluntarily discharged herself from hospital. Although the practitioner had offered to interview the mother within half an hour another doctor was called in and no further attempt was made to obtain the services of the responsible practitioner. The committee found that there was no failure on the part of the practitioner to comply with the terms of service and that the cost of treatment obtained from the second doctor was not reasonably and necessarily incurred.

The case was dealt with under 6 (1) (b) of the rules for the administration of medical benefit; when the subcommittee are of opinion that the case is one which can be disposed of on the written statements of the parties, and both parties agree, there is no hearing.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Whitsuntide Adjournment

THE House of Lords adjourned for the Whitsuntide recess on Thursday, June 6th, until June 17th. The House of Commons adjourned on Friday, June 7th, until June 17th.

The Housing Bill in the Lords

On June 5th in the House of Lords Viscount HALIFAX, President of the Board of Education, moved the second reading of the Housing Bill. He said that the suspension of building during the war, the dislocation of labour and material supplies which followed the war, the suspension of emigration, and the steady increase of population amounting to some 2,000,000 persons between 1921 and 1931, taken together with the need of improving then existing conditions had been the occasion of a whole series of Housing Acts and of the provision of something like 2,500,000 houses between 1919 and 1934, estimated to give accommodation to some 7,000,000 persons. But all that great provision of houses had made no more than a negligible contribution towards the solution of the worst housing evils—namely, slums and overcrowding—for the reason, he supposed, that they had failed to define their objects with sufficient clearness and to satisfy themselves that they had adequate powers to achieve them. It was the recognition of that fact that had induced the present Government for the first time, he believed, in the history of housing reform to try to attack the problem on what they believed to be more definite and more logical lines. In that policy the Government had accordingly sought to proceed by three quite distinct and consecutive stages. The first stage was taken in 1933 when they withdrew the subsidies for new houses at large, thus liberating as far as possible the instrument of private enterprise from the shackles of subsidy competition and ensuring that where subsidies were still essential the available public money should not be dissipated but should be used only where the principal object of getting houses of the right sort and in the right place could not be achieved without them. The number of houses that were built by private enterprise in the half-year ending in March, 1934, was over 120,000; in the next six months it was 137,000; and in the six months recently ended it was just on 150,000. That last figure represented a total of about 300,000 houses a year, which compares with an annual total of about 200,000 before the passing of the 1933 Act, and it was interesting to add that this figure of 300,000 houses a year was estimated to include not less than 100,000 Class C houses. Those figures were sufficient justification of the policy that the 1933 Act embodied.

Generally speaking, present-day building costs and rates of interest when taken with the Exchequer subsidy under the 1930 Act made it possible to charge an inclusive rent of not more than 10s. a week, and many local authorities charged rents well below that sum. There was a provision in this

Bill for the unification of housing accounts which it was anticipated would in future give local authorities freedom to use the resources which they obtained from the Exchequer to the greatest possible advantage; and further, the Bill expressly recognised the duty of granting rebates of rent to persons whose financial position rendered that course necessary and justifiable. The second stage in the housing policy of the Government was to apply the Act of 1930 to a definite five-year programme of slum clearance. Here, again, he thought they might claim that the campaign against the slums had been so far an unqualified success. The number of houses promised by local authorities since the policy was launched had been over 100,000, and he believed that well over 26,000 were actually under construction at the end of April last, and there was every reason for thinking that the five-year plan for replacing houses in which people ought not to be asked to live by houses in which they might take some pride would be carried out in five years, except in such areas as London, where it had always been recognised that the amount of work to be done must require a longer time.

The third stage in the Government's housing policy was that which dealt with the problem of overcrowding. It was with that aspect of the question that the present Bill was designed to deal. The Bill laid down a standard based on the two obvious principles that proper separation of the sexes should be observed and that the houses should not be occupied by more people than they could properly accommodate. He was convinced that no lower standards than those set out in the Bill could secure the objects which the Government had in view. To those who might object that the standards prescribed were too low, he would point out that those standards represented neither the ideals of the Government nor the realities which in most cases would no doubt be attained. He suggested, however, that in the application for the first time of penal standards it was necessary to temper zeal for what might be with a practical recognition of what was; and that it would be for the national conscience to show that they were obsolete. To meet criticism which had been made in some quarters he would point out that the standard on which new houses were to be provided was not the penal standard of this Bill but the much more liberal standard laid down in Section 37 of the Act of 1930. These standards were intended to be for general application, but it was recognised that some discretion must be allowed in their application. The first part of their task then was the preparation of standards; the second was to see that such standards were enforced; and the third, and most important, without which enforcement would obviously be impossible, was the provision of suitable alternative accommodation.

The Bill was read a second time.

University of Durham Bill

Viscount HALIFAX presented a Bill to make further provision with respect to the University of Durham and its constituent divisions and colleges.

The Bill was read a first time.

Voluntary Hospitals (Paying Patients) Bill

The Voluntary Hospitals (Paying Patients) Bill was read the third time and passed.

Bills Advanced

On June 6th, in the House of Lords, the Restriction of Ribbon Development Bill and the Unemployment Assistance (Temporary Provisions) (No. 2) Bill were read the third time.

In the House of Commons on June 5th the Government of India Bill was read the third time.

National Health Insurance Bill

In the House of Commons on June 6th Sir HILTON YOUNG, Minister of Health, moved the second reading of the National Health Insurance and Contributory Pensions Bill. The measure, he said, was one of great social importance to very wide classes in the country. The great depression had affected the whole basis of the National Health Insurance scheme adversely. How adversely the scheme had been affected by the general depression and the unemployment was closely revealed on the occasion of the Third Valuation, when the Government actuary's report disclosed that, owing to the diminution in the contribution income on account of unemployment, great evils were impending over the National Health Insurance system. Many of the approved societies were threatened with being driven down into a deficiency, and it became urgently necessary to take emergency measures to protect the basis of National Health Insurance for the preservation of its solvency and of the contributory principle. Had such measures not been adopted National Health Insurance would have followed the course of unemployment on its downward track which would have led to complete financial disaster. At that time, also, owing to the general adverse state of the national finances, the Exchequer was unable to give any exceptional and additional financial assistance to the National Health Insurance scheme, and for that reason the scheme had to be fortified and rebased without help from outside. That was done by the Act of 1932. What were the measures taken in 1932 to protect health insurance and its continuance from the evils which then threatened it owing to the great depression

In the first place, it was found impossible to continue some of the special concessions made to the unemployed in easier financial times. It was found impossible to continue them indefinitely from year to year, owing to the fact that the unemployed had been for a long period unable, on account of their unemployment, to make their contributions to the scheme. Secondly, it was found impossible to continue the system which had been introduced in 1928 for the further relief of the unemployed—the system under which the unemployed were credited with all arrears of contributions due to unemployment, so that in weeks of unemployment they were excused all contributions and the arrears which subsequently arose in their contribution records had no effect in reducing their cash benefits in the subsequent contribution year. That was the second concession which it was necessary partially to diminish in 1932 by going back on the 1928 arrangement to the extent that only half of the contributions due to unemployment were thereafter excused. That meant a relief of £1,500,000 a year in the finances of the approved societies.

SICKNESS EXPERIENCE OF WOMEN

There was another matter which was dealt with on a rather different footing. The experience of the sickness of women under the scheme had been found to exceed expectations so that on an actuarial basis the scheme was unable to maintain the benefits it was originally designed to maintain. Action was taken to protect the finances of the scheme by reducing the benefits to women to the amount which actuarially the scheme was capable of maintaining. That stood on a different basis; it was not directly related to the bad times. The subsequent experience of women's sickness had tended to confirm the forecast that was then made and to justify the reductions as being sound in relation to the actuarial aspects of this scheme, and it was not now proposed to make any further change in the particular matter of women's benefits.

In the health part of the scheme, said Sir Hilton, the structure was underpinned, but at the same time they had protected the highly valued pension rights from any source of interference. All the unemployed were continued in pension rights until the close of the current year, that was until Jan. 1st, 1936. Such was the state of affairs which was left by the Act of 1932. Speaking on behalf of the Government at the time of the passage of that Act he had said that if and when there was an improvement in national conditions sufficient to make it possible to reverse any part of the then withdrawal of concessions it would be the duty of the Government to again propose concessions of that sort. The review of the decennial period had now been received from the Government actuary. He did not want in any way to exaggerate, but the state of affairs was marked by one clear characteristic, and that was a very great improvement in all those factors of national prosperity which were relevant to the Government of national health insurance and pension schemes.

The optimists of three years had been justified, and within the time of the decennial review they were able financially to reconsider the steps it was necessary to take in order to preserve the solvency of this scheme and protect the benefits of the insured. The unemployment figure, the underlying factor, which was then approximately 2,750,000 on the live register, now stood at approximately 2,000,000. The reduction of 750,000 persons was reflected in the finances of the insurance scheme by this most vital circumstance that the contribution increment available to the scheme between 1932 and 1934—the last year with regard to which he had the figures available—increased by £2,375,000 a year, a most encouraging circumstance and one which enabled them to take a different view of the state of affairs from that which it was necessary to take at the time of the great depression.

CONCESSIONS JUSTIFIED BY NATIONAL PROSPERITY

Another circumstance of very great significance in the general restoration of prosperity was the stabilisation of our national finances and the balancing of the budget. In the present Bill the Government fulfilled their undertaking by dealing with the pensions scheme before the beginning of 1936. They found themselves in a position to go back and to continue in national health insurance those who fell into unemployment from year to year without those limitations which on the previous occasion it was necessary to adopt. The result would be that they would secure to all one and three-quarter years on an average free insurance which was at present secured upon the termination of insurable employment. At the close of that period of free insurance, which everybody had, they dealt with the unemployed in this manner. Subject to a certain qualification, those who were unable to maintain their contributions by reason of unemployment would be maintained in insurance year by year if unemployment continued. Thus, if they were still unable to get work and so pay contributions, then, if unemployment was the cause of their contributions not being paid they would be continued in insurance from year to year indefinitely. (Cheers.) The continuance would not secure health insurance cash benefits. The benefits secured were medical benefit and additional treatment benefits, including institutional benefits of a medical sort.

Viscountess ASTOR asked if maternity benefit was secured.

Sir HILTON YOUNG: No, that is a cash benefit. Pension and medical benefits are secured indefinitely from year to year.

Persons who under the Act of 1932, owing to unemployment, had to have their health insurance benefits discontinued, were they, he asked, to be left out? The number involved in round figures was about 200,000 persons. A certain number had passed out of insurance already, and a certain number would come back again owing to re-employment. It was difficult to estimate how many, but on Jan. 1st next approximately 200,000 would be passing out of insurance for all purposes unless they were helped. He was fortunately now in a position to take power to make transitory regulations under the Bill which would enable him to prevent those who were going out of insurance on Jan. 1st from doing so and to bring all those who had gone out of insurance owing to unemployment back into insurance.

The condition for the continuance of insurance was that there should be ten years of continuous insurance when work ceased. Did this mean that many unemployed would be unable to be continued in insurance because they could not make good? The answer was No. Owing to successive Acts for continuance in insurance all unemployed persons with four years' continuous insurance and 160 contributions had in fact been continued in insurance from year to year. So that, generally speaking, the unemployed would not find any difficulty in fulfilling this qualification. It might be inferred from the actuary's report that not more than 9 per cent. of the 200,000 persons to whom he had referred would fail to qualify under the 10 years' condition. The actuary estimated further that at least half of those would come back to employment within a short time. So that it was only about 5 per cent. of the 200,000 who would fall out of insurance for more than a short period. These would not only be people who were going out because of unemployment, but they would include people going out for different reasons, such as taking up uninsurable employment. But for the most part they would be young people with good prospects of coming back to insurance again. They retained the concession given in respect of pensions under the Act of 1932, that was an additional year of cover for pensions for those whofailed to satisfy the ten years' test but had a four years' record of continuous insurance.

DEALING WITH ARREARS

What could they do, Sir Hilton continued, under the arrears part of the scheme. Fortunately they were now in a position, as it were, to let out the slack they had to take up in 1932, and they were able with the increased contribution income and some financial help to go back to the full excusal of arrears, so that all arrears of contributions due to unemployment would be fully excused and would have no effect at all upon the cash benefits of the unemployed, as it was before 1932 and after 1928. That would mean a very great benefit on the cash side to millions of insured persons—something between 4,000,000 and 5,000,000 persons—and it would also certainly mean an enormous simplification of administration and saving of expense to the approved societies. Arrears for the year 1934–35 due to unemployment would be fully excused.

Mr. E. WILLIAMS: Excusal of arrears does not apply to 1933?

Sir HILTON YOUNG: No to 1934–35, so that for the current year it is retrospective to that extent.

There was another advantage to be derived. Many approved societies made use of surpluses to pay up arrears and so enabled the unemployed to get their cash benefits. Now that they were excusing their arrears those moneys would be released for additional benefits.

It would mean something like £300,000 a year to be released for additional benefits—a by-product of the main scheme. The finances of this proposal were simple. The Actuary's report on the decennial period showed that they could give this continuation of pension rights for the unemployed from year to year indefinitely in the manner he had described, and give it now in view of the existing state of the fund the reserves of which would be adequate until the next decennial period, 1946, and no further money would be required to finance this concession until that period. In 1946 the House could make fresh arrangements for Exchequer contributions to the pension fund, but until that period no fresh finance would be required. He would remind the House that under existing law there would be an automatic increase in the contributions for pensions at the end of the present year of 2*d*. for men, equally distributed between employer and employee and 1*d*. for women. A sum of about £1,500,000 a year was required to finance the excusal of arrears due to unemployment, and this included the much smaller sum necessary to finance the medical benefits for those who were continued in extended insurance.

The Government proposed to distribute the financial burden between the approved societies and the Exchequer, half being found by the approved societies and half by the Exchequer. They would find about £700,000 or £750,000 each. The form of the finance of the scheme was a pound for pound arrangement between the Exchequer and the approved societies. The approved societies met the burden by a general levy on contributions. The effect was to bring the societies with less unemployment to the assistance of those with more unemployment. For the first year they were able to finance the Exchequer contribution by appropriating a balance from the army, navy and air force fund.

Mr. Neil Maclean said that to the intentions of the Government as explained by Sir Hilton Young he took no exception, but in the opinion of the Labour party more might be done for those to whom the Minister of Health desired to give security of pension and security of benefits.

Mr. Graham White said that the Liberal party welcomed the Bill and they hoped that it might become law quickly with such modifications as might be necessary.

Mr. Morgan said the House ought to give particular attention to the way in which insured persons were treated. Generally speaking they were treated remarkably well, but there were cases of patients who were treated rather in a "panel" sort of way which the Minister might investigate. He did not know whether these panel doctors had too many patients on their lists, but these poor people had grounds for grumbling when they had to sit for a long time and get no proper treatment at the finish.

The Deputy Speaker (Sir D. Herbert) said that point could not be developed in this debate.

Mr. Llewellyn-Jones said the Minister had referred to the fact that he hoped not only that medical benefit would now be available to all men and women who had gone out through unemployment but that they would also be entitled to the additional treatment benefits. There was reason to anticipate that there might be difficulty in this connexion. The surpluses which would otherwise be available for members of approved societies would naturally be reduced as a result of the contribution of £750,000 a year by the approved societies towards the finance of the Bill. It would then be made more difficult for the societies to give the additional treatment benefits which everyone recognised were essential if medical benefit was to serve the purpose that it ought to serve. Take for instance the case of dental benefit. Unfortunately a large number of societies had already failed, owing to the drop in their reserves, to give any more dental benefit. He hoped that this or some future Government would deal with the situation on broader and more generous lines.

Viscountess Astor thought that the Minister should have made a greater provision for maternity benefit. She implored the Government to see whether they could not extend the period for maternity benefit even when the other cash benefits had come to an end.

Mr. Janner said that the suggested concession on maternity would not cost much money. There was considerable anxiety about insured persons being unable to obtain the right kind of specialist medical and surgical advice and that specialist treatment and diagnostic advice were not available for the insured person. In 1926 a large amount of money was diverted from the fund which was available for the purpose of supplying insurance benefits to those who came within the provisions of the Acts. He was sorry that it had not been found possible to give back a larger proportion of that sum in order to provide additional benefits. Health insurance funds were no longer yielding the same amount of interest as they did formerly and the Exchequer might well be called upon to contribute a larger amount.

Mr. Banfield said that hundreds of thousands of people had been looking to the Government to raise the income limit of insurability. If the Government were really going to do something big in the way of national health insurance they might consider this class of people above the £250 a year limit—the small shopkeeper and professional people—who declared that they could never see any reason why they were not given the opportunity to contribute to old age pensions and health insurance.

Mrs. Tate said there was a good deal to be said for Mr. Banfield's suggestion to overhaul the whole matter of national health insurance. She wished that the Minister could grant maternity benefit to the unemployed. The claims of women on the health insurance fund might be less severe if they could know that during a very anxious period in their lives they were still to draw their maternity benefit.

Sir Francis Fremantle said that such benefits as this Bill introduced were a hazard banking on the fact that we were probably going to move along the road to prosperity. Honest critics of this Bill would recognise that it could not have been introduced earlier because they were waiting for the report of the actuary and for the statistics from 1925 to 1932 on the working of the insurance system. This Bill had the great advantage of producing a more uniform, sensible and business-like system of administration. It also set up reasonable conditions under which the insurance status could be maintained. He joined with those who wished that it were possible to provide further maternity benefit, but again that was a question of expense, as it was with other benefits, including medical benefit. He wondered if the Minister had it in his mind to bring in during the autumn, and in the last session of this Parliament, that Maternity Bill of which they had heard so much, and whether it would be possible in that measure to make maternity provision for all the insured people. There was also a general feeling in regard to ordinary medical benefit—he was not now speaking of the cash benefit—that it was a hardship that the insured person should have to leave the doctor of his choice, who was used to him, and to whom he was used, and to go to the public assistance doctor, and then later on back to his own doctor. Now that they were accustomed to the panel doctor and public assistance system some arrangement ought to be made which would apply equally to insured and non-insured persons as regarded medical benefit and treatment, and he hoped that there would be such an arrangement before very long.

Mr. Clarke appealed to the Minister to insert a clause in the Bill to provide for the insurance of boys and girls between the ages of 14 and 16. At present, he said, there was no organised provision for the medical treatment of boys and girls between these ages. Secondly, this was a critical period of growth when neglect might cause irreparable damage. Boys and girls were subject to considerable strain when they first entered employment. Thirdly, the examinations by certifying surgeons under the Factory Acts were confined to a section of the juvenile population and were merely designed to prevent boys and girls with health defects from entering industrial employment; there was no provision for remedying any of the defects discovered. Fourthly, unemployed boys and girls joining junior instruction centres and classes might be treated by school medical officers and it seemed anomalous that the unemployed in this respect should be provided for while the employed were not.

Dr. O'Donovan said that Parliament entrusted a great deal of the financial help of the sick to the approved societies; but such societies once they had the millions of the public in their custody husbanded those millions with a care that had the full approval of the Treasury, but was often a source of grave disquiet to the doctors and to the sick throughout the country. Ordinarily a medical certificate was given in good faith to a sick person, but the impish ingenuity of the skilled advisers of the approved societies could see many outlets for the unwary disbursement of public money through medical certificates written in good faith but without lawyer-like skill; and while those difficulties were being cleared up by leisurely correspondence the sick person often waited weeks for the financial assistance that was so pressingly necessary to him. When the sickness became a matter of litigation so that the approved societies and the insurance companies, both having skilled professional advisers, were set in opposition to one another the needy sick person might wait weeks and months for any assistance from either side until the eminent lawyers and specialists, with the help of the judiciary had come to some conclusion and then only were his needs met. It was occasionally possible for the two sides to come to some temporary compromise as to which should pay in the interim, but he noticed in his work, and many of his brothers also noticed, that when the House of Commons wished to help the sick instantly the skilled professional advisers of approved societies carrying out their very proper work of the custody of their funds, put a very high barrier between the poor sick man and the money that he might have.

They had been told that it would be advisable for additional benefits to be granted. It had been suggested that these additional benefits might be maternal benefits and dental benefits, but he would put in a prior plea before these that specialist advice be made more available through the Ministry of Health for panel doctors up and down the country. It was not dignified or proper that this service should depend for its ultimate efficiency upon the free advice of consultants up and down the country. The more the panel system was improved and extended and the more medical benefits were extended among the poor people, the more patients would be found to need specialist advice. The out-patient departments of all the great hospitals were being more and more crowded by patients sent to them in pursuit of their proper aims by doctors whose work was safeguarded and increased by this amending Bill. Before they considered dental benefit they might turn their minds to the extension of maternity benefit.

There was, said Dr. O'Donovan, one other matter to which he would like to refer. If the age-groups of population in this country were to change greatly the actuarial provisions for extended benefit would be rendered very shaky. If they were to have therefore through a fall in the birth-rate an increasing aged population then their figures that night were based upon a shifting basis. He would very much like to hear from the Minister if the change in the birth-rate and the change in the age-groups of the population, which were referred to repeatedly in specialist papers on this matter, were constantly and frequently under review by his actuarial advisers.

CONSOLIDATION OF HEALTH INSURANCE ACTS PROMISED

Mr. SHAKESPEARE, Parliamentary Secretary to the Ministry of Health, replying to the debate, said that with regard to the question of the gap in insurance between the ages of 14 and 16 he was in sympathy with the demand for medical benefit. They would all like to see that gap removed, but they had not the finances to do it at the moment, and they must leave something for posterity. The Minister authorised him to say that it was the intention of the Government to consolidate the Health Insurance Acts as soon as possible. That would be to the benefit of everybody.

The Bill was read a second time and committed to a Committee of the whole House.

HOUSE OF COMMONS

WEDNESDAY, JUNE 5TH

Malaria in Ceylon

Captain PETER MACDONALD asked the Secretary of State for the Colonies, whether his attention had been called to the fact that the total number of deaths from malaria in Ceylon amounted to 82,637 for the six months November to April; and what special steps had been taken by the government of Ceylon to deal with this emergency.—Sir PHILIP CUNLIFFE-LISTER replied: I have not yet received reports from the Governor of Ceylon covering the period referred to in the question. As regards the special steps taken by the Government of Ceylon, I would refer my hon. friend to the full reply which I gave on March 27th. Since that reply was given the special officer whom I then mentioned, Colonel Gill, has arrived in Ceylon and is engaged in carrying out his investigations.

Play-streets for Children

Mrs. RUNGE asked the Minister of Transport, if he would consider taking steps to effect the closing of certain streets to traffic in the poorer districts of the towns for two hours an evening in the summer-time, so that the children could play in them without risk of accident.—Mr. HORE-BELISHA replied: I have, in collaboration with the Metropolitan boroughs of Southwark and Paddington, arranged, by way of experiment, for six streets to be set aside as play streets for children and I have given notice of my intention to make regulations closing these streets to through traffic.

Medical Examinations at Barlinnie Prison

Mr. LEONARD asked the Secretary of State for Scotland if he was aware that prisoners who had been admitted to Barlinnie about 1 P.M. were, after reception formalities, placed separately in extremely small cubicles and frequently kept there for several hours pending examination by the medical officer; that the cubicles referred to had no conveniences necessary for such extended occupancy; and if he would ensure that in future medical examinations would be expeditiously made or more suitable accommodation provided.—Sir GODFREY COLLINS replied: Prisoners received at Barlinnie about 1 P.M. are kept in small cubicles until medically examined. Untried prisoners are examined at 2 P.M., but the examination of convicted prisoners is sometimes deferred until 3.30 P.M. I am satisfied that there is no undue delay in conducting the medical examinations, and that otherwise the arrangements are adequate.

Scabies at Barlinnie Prison

Mr. LEONARD asked the Secretary of State for Scotland how many long-sentence-prisoners in Barlinnie prison during the last 12 months had contracted scabies after completing several months of their sentence through contact with dirty closet seats; and if he would take steps to ensure that the cleansing of closets was more effectively performed.—Sir GODFREY COLLINS replied: During the past twelve months no prisoner in Barlinnie Prison has contracted scabies from the cause mentioned. The accommodation in question is subjected daily to a scrupulous cleansing and is regularly inspected.

Mr. LEONARD: If I give the right hon. gentleman some details will he go further into the matter?

Sir G. COLLINS: Most decidedly.

THURSDAY, JUNE 6TH

National Health Insurance (Ophthalmic Benefit)

Sir JOHN WALLACE asked the Minister of Health, whether his department had now considered the final report of the ophthalmic benefit joint committee; and whether he proposed to introduce legislation on the basis of the Report.—Sir HILTON YOUNG replied: The Report to which my hon. friend refers is still under consideration. I regret, therefore, that I am not yet in a position to reply to the second part of the question.

Deaf and Dumb

Dr. ADDISON asked the Minister of Health whether he was prepared to introduce legislation giving to deaf and dumb persons similar benefits as well as facilities for training as were afforded to the blind under the Blind Persons Act.—Sir HILTON YOUNG replied: No, Sir. I am not satisfied that there is need for such legislation.

Inquiry into Nutrition of Children

Dr. ADDISON asked the Minister of Health whether he would publish the findings of the memorandum on the nutrition of children, prepared by the Economic Advisory

Council last year and any other Reports on kindred subjects submitted to his department which had led to the appointment of the special committee to report on the nutrition of the people, which had recently been announced. —Sir Hilton Young replied: As regards the memorandum of the Economic Advisory Council, I can only refer to the reply given to the right hon. Member by the Prime Minister in February (see The Lancet, Feb. 23rd, p. 466). As regards the rest of the question, the right hon. Member appears to be under some misapprehension. The Committee to which he refers is a standing advisory committee to assist myself and my right hon. friend the Secretary of State for Scotland with advice on problems of nutrition. It takes the place of a smaller and purely technical advisory committee which was appointed in 1931 by the right hon. Member for Wakefield (Mr. Greenwood) to perform the same service for the Ministry of Health alone.

Dr. Addison: Will the right hon. gentleman communicate to the House the information which led him to make this enlargement of the committee and ask the committee to conduct these wide researches?

Sir Hilton Young: I am always prepared on appropriate occasions to communicate all such information to the House.

Price of Milk Supplied to School-children

Mr. Thomas Williams asked the Minister of Agriculture the average price paid to producers and retailers for all milk sold to school-children.—Mr. Elliot replied: Milk supplied under the Milk in Schools arrangements brings to the producer who sells by wholesale the pool price for his region, less carriage and handling charges. The average pool price for the period from the inception of the arrangements up to the end of April was 13·59*d.* per gallon. The producer-retailer supplying milk for schools receives the actual wholesale price plus a distribution allowance of 6*d.* per gallon, and is charged the licensed retailers' contribution under the Milk Marketing Scheme. The average wholesale price for the seven months up to the end of April was 1*s.* 4·43*d.* per gallon, and the average producer-retailers' gross contribution was 2·51*d.* per gallon. The ordinary retailer's margin for distribution of school milk is also 6*d.* per gallon.

Burning Coal Bings

Mr. Neil Maclean asked the Secretary of State for Scotland whether he was aware of the complaints made in Lanarkshire against the coal bings which were burning there and because of the fumes which were a menace to the health of the people; and what action he proposed to take against the parties responsible.—Sir Godfrey Collins replied: The matter referred to is primarily one for the local authority under the Public Health (Scotland) Act, 1897. Only one complaint has been made to the Department of Health for Scotland in regard to burning bings in Lanarkshire. As a result of inspection the owners of this bing have undertaken to consider what action can be taken to extinguish the fire.

Alleged Ill-treatment of Defective Boy

Mr. Burnett asked the Secretary of State for Scotland whether his attention had been drawn to a case at the Aberdeen sheriff court, on May 23rd, in which a farmer was convicted of ill-treatment of a boy of 18 under his charge on licence from Rossie Farm School, Angus; whether he was aware that the boy was beaten on the body and legs with fists and with a stick, kicked on the body and legs, and submerged in a trough of water, and that the boy was stated to be on the border-line of a mental defective; and what steps were being taken to ensure that boys sent out from a reformatory on licence were protected from such brutality.—Sir G. Collins replied: My attention has been drawn to this deplorable case and to the particulars stated. The employer has been convicted on the charge of assault and sentenced to two months' imprisonment. With regard to the last part of the question, the managers of approved schools maintain close touch with the young persons who are released on licence. In this case I am informed that the headmaster of the school wrote to the boy six times during the seven months period of the boy's employment at the farm. Only one reply was received and it contained no complaint. Various reports were received from the employer none of which contained any indication of serious difficulty. The headmaster of this school, who is a man of outstanding reputation in reformatory school work, has placed 1500 boys in satisfactory employment in the past 35 years and he has never before had a case such as this. I am having the records of employment of young persons released on licence from approved schools during the last ten years specially examined, in order to ascertain whether there is any general ground for instituting a more thorough and systematic supervision over such employments.

Birth-rate: Effect on Social Services

Dr. O'Donovan asked the Minister of Health what was the nature of the personnel and organisation within his department charged with the duty to watch and advise him upon the effects of the trend of the birth-rate upon housing and other social services in being or under discussion for which he was or might be responsible to Parliament.—Sir Hilton Young replied: As my hon. friend is aware, the Registrar-General, whose Department is within my ministerial responsibility, has under continual study the nature and direction of all the elements of population movement, the handling of which calls for general statistical experience, prior to their application to particular administrative problems. The Registrar-General is in frequent consultation with the principal officers of the Department with a view to the development of useful lines of inquiry and the satisfaction of particular needs; and data as to the general population prospects and the results of special studies are made available to them either in departmental papers or in the Registrar-General's standard publications. This material is applied to administrative questions in the case of any particular subject matter by the officers by whom I am advised in that connexion.

Housing Bill and the Minimum Size of Rooms

Mr. Joel asked the Minister of Health whether, in view of the proposal in the Housing Bill under which subsidies would be granted towards the construction of houses, he proposed to suggest to local authorities receiving such subsidy that bedrooms of less than 70 square feet should not be constructed, in view of the fact that under the Bill in question such rooms were only assessed at being fit for occupation by a child under 10 years of age.—Sir Hilton Young replied: No, Sir. The considerations affecting the standard of re-housing accommodation provided by local authorities and those relating to the penal standard proposed in the Housing Bill are quite different and the two standards cannot appropriately be correlated in the manner proposed.

Warwickshire and Coventry Mental Hospital. A large nurses' home has been opened at this hospital, providing accommodation for 21 sisters and 95 nurses. The cost has been £39,000.

Education for Gas Warfare.—Mr. Davidson Pratt, F.I.C., secretary of the Association of British Chemical Manufacturers, gave a lecture last Wednesday to the British Science Guild in which he urged that the civil population should be instructed in methods of defence against gas attacks in war, more especially from the air. Gas, he said, had a devastating effect on the morale of people ignorant of its properties and uninstructed in methods of defence, and a country's lack of preparation in this respect might well induce an enemy to attempt a speedy victory. Reduced to its elements, the scheme of defence required that the general public should keep out of contact with gas, whether as liquid or vapour, by staying in gas-protected rooms till the raid is over and the area cleared up, and that there should be an organisation for the de-contamination of the areas affected and the first-aid treatment of those who have been exposed to gas. The success of the scheme would depend entirely on the behaviour of the population, and it was therefore important that people should be imbued with the proper psychological reaction. Mr. Pratt believes that the destructive power of gas attack from the air has been grossly exaggerated.

MEDICAL NEWS

University of Oxford

On June 8th the degree of doctor of medicine was conferred on C. Raymond Greene, and of bachelor of medicine on J. E. G. Pearson.

University of Cambridge

The degree of Sc.D. has been conferred on Mr. Leslie Harris, D.Sc., director of the Medical Research Council's nutritional laboratory at Cambridge University.

Dr. C. H. Whittle has been appointed as delegate of the University to the ninth international congress of dermatologists which is being held in Budapest in September.

University of London

At recent examinations the following candidates were successful :—

THIRD EXAMINATION FOR M.B., B.S.

Honours.—J. R. Forbes (*a*), Guy's ; G. W. Hayward, (*a*, *b*, *c*, *d*, *e*, *Univ. Medal*), St. Bart.'s ; G. W. Hearn (*c*), St. Thomas's ; Edward McLellan (*d*), St. George's ; and James Marshall (*a*, *e*), London.

(*a*) Distinguished in medicine ; (*b*) distinguished in pathology ; (*c*) distinguished in forensic medicine and hygiene ; (*d*) distinguished in surgery ; (*e*) distinguished in obstetrics and gynæcology.

Pass.—E. C. Atkinson, St. Bart.'s ; H. H. Atkinson, Univ. Coll. ; Barbara Bailey, Roy. Free ; T. A. Baldwin, Univ. Coll. ; E. B. D. Bangay and D. S. D. Barber, St. Bart.'s ; G. W. Bender, St. Mary's ; Brenda G. Billings, Roy. Free ; G. L. Bohn, St. Bart.'s ; A. P. Booth, London ; P. I. Boyd, Univ. Coll. ; D. J. T. Brinkworth, Middlesex ; I. A. Cathie, Guy's ; R. M. Clarke, Middlesex ; C. W. J. Claydon, King's Coll. ; F. T. Clive, St. Thomas's ; V. H. J. Davies, Charing Cross ; D. W. A. Degazon, Univ. Coll. ; Audrey P. Dence, Roy. Free ; Leslie Dexter and P. E. Dipple, St. Bart.'s ; Lynette Dowsett, Roy. Free ; F. C. Durbin, St. Thomas's ; H. A. Eason, London ; Evelyn J. Forgan, Roy. Free ; J. F. A. Forster, Guy's ; Sheila M. Franklin and Joyce C. Goodchild, Roy. Free ; I. H. Griffiths, Middlesex ; W. E. Hadden, St. Thomas's ; Marjorie K. Hall, Roy. Free ; P. G. F. Harvey, St. Bart.'s ; D. A. B. Hopkin, St. Mary's ; A. [illegible] W. Houghton, St. Bart.'s ; I. H. Jenkins, [illegible] Johnston, King's Coll. ; A. E. Jones, G[illegible] Bart.'s ; J. G. Jones and W. L. Kerr, King's Coll. ; Abraham Lasnick, Univ. Coll. ; J. B. H. McArthur, Guy's ; J. J. McCann, St. Thomas's ; Arnold Moore, Univ. Coll. ; Elizabeth C. Morris, Roy. Free ; R. B. Morton, St. Thomas's ; R. F. Mowll, King's Coll. ; H. E. Offord, St. George's ; E. D. Page, St. Mary's ; H. S. Pasmore, Univ. Coll. ; Geoffrey Phipps, St. Thomas's ; D. S. Piper and A. G. Potts, Guy's ; Marjorie A. Powys, Roy. Free ; V. B. Reckitt, Guy's ; A. H. W. Roffey, King's Coll. ; K. B. Rogers, St. Mary's ; C. G. Roworth, J. G. Sheldon, and R. H. D. Short, Univ. Coll. ; Frank Summers, King's Coll. ; W. H. Summerskill, Guy's ; Margaret E. Sutherland, Roy. Free ; B. A. Thomas and D. M. Thomson, St. Bart.'s ; W. F. Townsend-Coles, London ; Enid L. Weatherhead, Roy. Free ; F. H. Weston, Guy's ; and C. W. K. Willard, Univ. Coll.

The following students have passed in one of the two groups of subjects :—

Group I.—Bernard Cates, St. Bart.'s ; Robert Cox, Westminster ; Kathleen Craddock, Roy. Free ; J. V. Dacie, King's Coll. ; A. M. Desmond, London ; W. J. M. Evans, Univ. Coll., Cardiff ; H. C. H. Higginson, St. Bart.'s ; C. E. W. Hoar, Westminster ; Tobias Levitt, Middlesex ; W. N. Mann, Guy's ; R. L. Moody, St. Thomas's ; Margaret J. Moore, Roy. Free ; C. J. S. O'Malley, St. Thomas's ; G. H. C. Ovens, St. Mary's ; F. D. Paterson, St. Mary's ; Millicent I. Rowland, Roy. Free ; J. K. Samuel, St. Thomas's ; Catherine M. Whitestone, Univ. Coll. ; and B. L. E. Wong, Guy's.

Group II.—Mary J. Bartlett and Beatrice A. Blake, Roy. Free ; C. J. F. Blumenthal, Guy's ; Margaret Brodigan and A. M. Cusack, Univ. Coll. ; Dorothy S. R. Drew, Roy. Free ; J. A. C. Franklin, St. Thomas's ; L. D. B. Frost, St. Bart.'s ; Philip Glazer, King's Coll. ; J. R. Hill, St. Bart.'s ; J. H. Lawrence, Univ. Coll. ; J. I. Lesh, St. Thomas's ; H. M. McGladdery, St. Bart.'s ; Margaret I. McHaffie, Roy. Free ; J. I. C. Mason, St. Bart.'s ; Margaret J. Montrose, Roy Free ; W. L. Ogle, Guy's ; E. U. H. Pentreath, St. Bart.'s ; J. B. Phillips, Univ. Coll., Cardiff ; Jean Ross, Univ. Coll. ; D. J. Sheehan, St. Bart.'s ; B. McN. Truscott, Middlesex ; and C. E. G. Wickham, St. Thomas's.

Semon Lecture

This annual lecture will be delivered on Thursday, Oct. 31st, at 5 P.M., at the Royal Society of Medicine, 1, Wimpole-street. The lecturer, Sir StClair Thomson, has chosen as his subject : The Defences of the Upper Respiratory Tract.

Teddington Memorial Hospital

Lady Dawson of Penn recently opened this hospital, the foundation-stone of which was laid by Lord Dawson five years ago. The hospital began in a two-roomed villa some 60 years ago.

Royal College of Surgeons of England

At the primary examination for the fellowship held from May 28th to June 8th, 222 candidates presented themselves, of whom 84 were approved and 138 were rejected. The following are the names and medical schools of the successful candidates :—

D. A. Andersen, M.B. Lond., Middlesex and Univ. Coll ; A. G. Apley, Univ. Coll. ; D. W. Ashcroft, M.B. Otago, Middlesex and Univ. Coll. ; H. C. Barry, Sydney and Oxford ; A. D. Bateman, St. Bart.'s ; S. A. Beards, M.S. Lond. ; T. Beath, M.D. Toronto, Univ. Coll. ; J. P. Bentley, King's Coll. ; D. Bhatia, M.B. Punjab, Univ. Coll. ; R. D. Blachford, Guy's ; J. G. Bonnin, M.B. Melb., Middlesex and Univ. Coll. ; N. J. Bonnin, M.B. Adelaide, Middlesex and Univ. Coll. ; Janet E. Bottomley, Lond. School of Medicine for Women ; J. F. Bourdillon, Oxford and St. Bart.'s ; W. S. Campbell, M.B. Belf. ; W. M. Capper, M.B. Lond., St. Bart.'s ; S. R. Chandra, M.B. Calcutta, St. Bart.'s ; J. M. P. Clark, M.B. Leeds ; C. S. Day, M.D. Toronto, Manch. and Middlesex ; T. M. J. d'Offay, M.B. Edin., Edin. and Sheff. ; E. G. Dolton, Camb. and St. Thos. ; Margaret M. Ferguson, M.B. Manch. ; R. W. S. Fox, M.B. Melb., Middlesex ; E. H. W. Gifford, M.B. N.Z., Middlesex ; R. G. Gilbert, M.B. Lond., St. Bart.'s and Guy's ; M. Gordon, M.R.C.S., Univ. Coll. and Middlesex ; A. S. Gray, M.B. Otago, Univ. Coll. ; A. O. Green, M.D. Melb., Middlesex ; M. H Harmer, Camb. and St. Bart.'s ; R. F. E. Harrington, Middlesex and Univ. Coll. ; J. Henderson, M.B. Durh., Middlesex ; J. F. Heslop, M.B. Manch. ; M. J. Horgan, M.B. Dubl., St. Mary's ; R. A. Hughes, M.B. Liverp. ; L. A. Ives, St. Bart.'s ; J. I. P. James, Univ. Coll. ; C. C. Jeffery, M.R.C.S., London ; H. Kander, St. Mary's ; M. B. Khan, M.B. Leeds, Univ. Coll. and Middlesex ; D. Landsborough, London ; C. H. W. Lawes, M.B. Sydney, Middlesex ; A. G. Leigh, M.B. Liverp. ; J. C. Luke, M.D. McGill, Middlesex, St. Bart.'s, and Univ. Coll. ; K. Lumsden, M.R.C.S., St. Bart.'s and Middlesex ; A. N. McCrea, M.B. Camb., St. Mary's ; O. T. Mansfield, Middlesex ; R. W. Mason, Camb. and Middlesex ; S. K. Menon, M.B. Bombay, Univ. Coll. ; A. D. Messent, St. Bart.'s ; A. Miller, M.B. Camb., St. Mary's ; W. G. Mills, Birm. ; T. Moore, M.B. Durh. ; M. P. Morel, M.R.C.S., St. Bart.'s and St. Mary's ; J. Moroney, Liverp. ; D. V. Morse, St. Bart.'s ; A. Mukerji, M.B. Calcutta, Univ. Coll. ; J. H. Mulvany, M.R.C.P. Lond., King's Coll. ; C. J. B. Murray, M.R.C.S., Middlesex ; J. D. N. Nabarro, Univ. Coll. ; A. A. K. Naqsh-Bandi, Punjab and London ; D. P. O'Brien, M.B. N.Z., Otago ; H. Park, M.B. Edin., St. Mary's and Univ. Coll. ; R. A Piachaud, M.R.C.S., Univ. Coll. and Middlesex ; C. G. Rob, Camb. and St. Thos. ; A. G. Ross, M.B. Belf., St. Mary's and Middlesex ; R. H. Shah, M.R.C.S., Univ. Coll. ; C. J. C. Siggers, M.R.C.S., Guy's and Middlesex ; B. N. Sinha, M.R.C.S., Univ. Coll. ; A. F. Smith, Oxford, St. Mary's and London ; Margaret D. Snelling, London School of Medicine for Women ; H. Spencer, St. Mary's ; R. A. Stephen, M.D. Aberd. ; J. C. Stewart, M.B. Melb., Middlesex ; F. E. Stock, King's Coll. ; H. Treissman, M.B. Lond., M.R.C.S., St. Bart.'s ; O. J. Vaughan-Jackson, B.M. Oxon., London ; E. Vernon, M.B. Manch. ; Phyllis Wade, M.B. Lond., London School of Medicine for Women and Univ. Coll. ; N. J. Weinberg, M.B. Wits'rand, Lond. and Middlesex ; W. F. Whelton, M.B. Irel., Middlesex ; Aileen E. M. Whetnall, King's Coll. ; G. Williams, M.R.C.S., St. Mary's and St. Thos. ; R. A. M. Yeates, M.B. Sydney, Middlesex and Univ. Coll. ; F. R. Yousry, M.B. Cairo, Univ. Coll. and Middlesex.

London Hospital Medical College

On Thursday, July 11th, at 3 P.M., Mr. John Masefield, O.M., will distribute the prizes to the students of the London Hospital medical college and dental school.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on June 3rd Stanley Alstead (Glasgow), Richard Makram Ebeid (Egypt), and Walter Martin Nichols (Glasgow) were admitted to the fellowship.

Royal Society of Tropical Medicine and Hygiene

The annual general meeting of this society will be held on June 20th at Manson House (26, Portland-place, W.), at 8.51 P.M., when the new president, Sir Arthur Bagshawe, director of the Bureau of Hygiene and Tropical Diseases, will be inducted. The Manson medal will be presented to Dr. J. W. W. Stephens, F.R.S., emeritus professor of tropical medicine in the University of Liverpool, and the Chalmers medal to Dr. W. H. Taliaferro, professor of bacteriology in the Ogden School of Science, Chicago. Dr. S. Somasundram, physician to the Kandy Hospital, Ceylon, will afterwards give a demonstration of temperature charts showing the action of atebrin musonate in malaria. Sir John Megaw will open a discussion on typhus fever in the tropics, and other speakers will include Dr. William Fletcher and Mr. A. Felix, D.Sc.

Dr. Jules Gonin, whose death is reported, occupied the chair of ophthalmology at Lausanne and became famous as the inventor of the only successful treatment for detached retina.

Sir James Barrett, consulting surgeon to the Victorian Eye and Ear Hospital, and vice-chancellor of the University of Melbourne, has been appointed president-elect of the British Medical Association for 1935–36. Sir Richard Stawell, who was to have presided over the Association's Melbourne meeting in September, died on April 18th.

The tenth annual Macalister lecture will be delivered at the National Temperance Hospital on Thursday, June 20th, at 9 P.M., by Mr. Herbert J. Paterson, C.B.E., who will take for his subject "Medicine and Magic." Medical practitioners and their friends are invited to the lecture, at which light refreshment will be served, and communications should be addressed to the secretary, National Temperance Hospital, Hampstead-road, London, N.W.1.

International Association for Preventive Pædiatrics

The fifth conference of this association (the medical section of the Save the Children International Union) will be held at Basle, under the presidency of Prof. Wieland, on Sept. 20th and 21st. The subjects to be discussed are the avoidance of internal and external infection in children's hospitals, and the prevention of tuberculosis in schools. The secretary's address is 15, rue Lévrier, Geneva, Switzerland.

A Tour to Jugoslavia

La Nomade (a medical touring society) is organising a motor tour for medical men and their friends, in which the principal towns, spas, and watering-places of Jugoslavia will be visited. Basle will be the starting-point for the expedition on August 21st, and Jugoslavia will be reached by way of Zurich, Innsbruck, and Carinthia, the party arriving in Ljubljana on the 25th. The return journey will be through Trieste (Sept. 5th), the Italian lakes, and the St. Gothard pass, and the tour will end at Basle on Sept. 8th. The cost will be 2900 French francs, and further particulars may be had from Dr. Cavro, 15 rue Jules Ferry, Paris XIII.

British Association of Radiologists

This association, whose formation was described in our issue of May 4th (p. 1060), is holding its first annual meeting in Birmingham on July 12th and 13th under the presidency of Dr. J. F. Brailsford. After the presidential address a visit will be paid to the new hospital building, and in the afternoon an exhibition of radiograms of bones and joints will be held in the anatomical department of the University. The lord mayor of Birmingham will be the association's guest of honour at dinner in the evening. Next day will be devoted to communications and discussions on antenatal radiology (Dr. R. E. Roberts and Dr. L. A. Rowden), pre- and post-operative radiation for breast cancer (Dr. Douglas Webster), and spondylitis *adolescens* (Dr. Gilbert Scott). Proposal forms for membership and other information may be had from Dr. S. Cochrane Shanks (hon. secretary), 68, Harley-street, London, W.1.

Congresses in Russia

The date of the fifteenth International Physiological Congress, which is to take place in the U.S.S.R. under the presidency of Prof. Ivan Pavlov, has been definitely fixed for August 9th. From then until the 16th the sessions will be held in Leningrad; on the 17th and 18th the Congress will sit in Moscow. Five hundred delegates from other countries, including a hundred from Great Britain, have signified their intention to be present. The committee should be addressed at Leningrad, Main P.O., Box 13. It may also be noted that the Physiotherapeutic Congress will be held in Odessa from August 25th to 30th, particulars of which may be had from Dr. Shimshelevicz, B. Vorobinsky 7, Flat 5, Moscow 28. Information about travel arrangements and expenses for both congresses is obtainable from Intourist, Ltd., Bush House, London, W.C. 2.

Beit Memorial Trust

Prof. T. R. Elliott, F.R.S., director of the medical unit at University College Hospital, has been appointed a trustee of the Beit memorial fellowship for medical research in place of the late Sir John Rose Bradford.

Canterbury's New Hospital

The Duke of Kent will lay the foundation-stone of this hospital on July 12th. A sum of over £30,000 has still to be raised if the institution is to start clear of debt.

Lewes Victoria Hospital

The ordinary income for last year at this hospital was £3334 which was just sufficient to meet the expenditure. The penny fund has realised £984 during the year and in 11 years it has brought in well over £9000.

Donations and Bequests

Dr. Ernest Ofenheim, whose death we reported on March 9th, among other bequests to the St. John's Hospital, Lewisham, left £300 on trust to pay in perpetuity 1*d*. every Sunday morning to each patient in the hospital between the ages of 2 and 16.

Princess Beatrice Hospital, London

A campaign is to be inaugurated to raise £100,000 for this hospital, and £2000 has already been contributed by Mr. E. W. Meyerstein. The hospital is full to overflowing, and has no reserve beds for emergencies, while the accommodation for nurses is so unsuitable that the General Nursing Council cannot approve the hospital permanently as a training school.

Honour for a Medical Man

Dr. V. H. Wyatt Wingrave of Lyme Regis is to receive the freedom of Coventry, where he was born in 1858. Formerly pathologist to the Central London Throat and Ear Hospital, and dean of its medical college, Dr. Wingrave has for many years continued his pathological, literary, and archæological work in face of grave physical disability. He is the author (with the late Sir William Milligan) of "Diseases of the Ear" and of other medical works, and until lately has been hon. curator of the Lyme Regis museum which he founded some fifteen years ago. Because of the state of Dr. Wingrave's health the mayor of Coventry will travel to Lyme for the ceremony.

Royal Sanitary Institute

The annual health congress of this institute will be held at Bournemouth from July 15th to 20th under the presidency of Lord Malmesbury. Subjects for discussion include the new Housing Bill, rural water supplies, the future of the school medical service, open-air swimming baths, and town and country planning. Dr. Thomas Carnwath, deputy chief medical officer of the Ministry of Health will preside over the section of preventive medicine, and Dame Louise McIlroy, as president of the section of maternity, child welfare and school hygiene, will speak on diet deficiency in pregnancy. There will be a health exhibition in connexion with the congress. The secretary of the institute may be addressed at 90 Buckingham Palace-road, London, S.W.

Union Thérapeutique

The general assembly which will meet at the Paris Faculty of Medicine on Wednesday, Oct. 9th, will deal mainly with three topics: the male hormone introduced by Prof. G. Laroche, splanchnic surgery in arterial hypertension by Prof. René Fontaine (Strasbourg), antimonial compounds in therapy by Dr. J. La Barre (Brussels). The afternoon session, held jointly with the Société de Thérapeutique, will consider physiochemical and glandular equilibrium in the treatment of visceral spasms (Prof. Pende, Genoa); spasmogenic substances and their antagonists (Prof. Bürgi, Berne); sedative treatment of spasms (Dr. J. Decourt); and physiotherapy of spasms and visceral pains (Dr. Delherm). Inquiries should be addressed to the secretary-general, Dr. G. Leven, 24, rue Téhéran, Paris (8). The Union is an international association of doctors and biologists specially occupied with questions of treatment, the president being Prof. Maurice Loeper (Paris) and the British vice-president, Dr. E. P. Poulton.

Wembley Hospital

This hospital is planning a £95,000 extension scheme which will double the number of beds and provide new electrical, X ray, and other departments and a new nurses' home. The hospital has had to deal with over 10,000 road accidents cases during the last six years.

Bute Hospital, Luton

Miss Louisa Lye has left £24.000 and her Brighton residence to this hospital to establish a convalescent home to be known as the Thomas Lye Convalescent Home. She has bequeathed a further £2000 to endow a bed or beds in memory of her parents.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, June 18th.

General Meeting of Fellows. 5.30 P.M.

Psychiatry. 8.30 P.M. Prof. C. S. Myers, F.R.S., and Dr. A. Macrae: Vocational Guidance.

Thursday.

Dermatology. 5 P.M. (Cases at 4 P.M.) Dr. H. W. Barber: 1. Lichen Spinulosus with Cicatricial Alopecia.

Friday.

Obstetri [illegible] Miss E. H. Lepper: The [illegible] umours of the Ovary. Mr. [illegible] Cast in Suspected Ectopic Gestation. Dr. Chassar Moir: The Merits and Demerits of Oxytocic Drugs in the Post-partum Period.

EUGENICS SOCIETY.

Tuesday, June 18th.—5.15 P.M. (Rooms of the Linnean Society, Burlington House. Piccadilly. W.). Dr. T. Drummond Shiels, Mr. C. V. Drysdale, D.Sc.: Are the Principles of Eugenics most favoured by a Socialist or Capitalist State of Society?

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE. 26, Portland-place, W.

Thursday, June 20th.—8.15 P.M., Annual General Meeting. Dr. S. Somasundram: Demonstration of Temperature Charts illustrating the Action of Atebrin Musonate in Malaria. Sir John Megaw. Dr. W. Fletcher. and Mr. A. Felix, D.Sc.: Typhus Fever in the Tropics.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, June 17th. to Saturday. June 22nd.—St. Peter's Hospital. Henrietta-street. W.C. All-day course in urology.—Prince of Wales's Hospital. N. All-day course in medicine, surgery, and the specialities.—London Lock Hospital, Dean-street. W. Afternoon course in venereal diseases.—Courses and clinics arranged by the fellowship are open only to members and associates.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

Thursday. June 20th.—2 P.M.. Dr. Donald Paterson: Artificial Feeding of Infants. 3 P.M., Dr. Signy: Pathological Demonstration.

Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

NATIONAL TEMPERANCE HOSPITAL. Hampstead-road, N.W.

Thursday, June 20th.—9 P.M.. Mr. Herbert Paterson: Medicine and Magic. (Macalister lecture.)

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.

Thursday, June 20th.—5 P.M.. Mr. Joseph Needham, Sc.D.: Problems of Chemical Embryology.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

Wednesday, June 19th.—3 P.M., Visit to High Wood Hospital for Children. Brentwood. (Dr. A. G. L. Reade.)

INSTITUTE OF MEDICAL PSYCHOLOGY. Malet-place. W.C.

Wednesday, June 19th.—3 P.M.. Dr. H. Crichton-Miller: Impotence. 4.30 P.M., Dr. Cedric Shaw: Differential Diagnosis.

INSTITUTE OF CHILD PSYCHOLOGY.

Wednesday, June 19th.—6.15 P.M. (Friends House. Euston-road, N.W.). Miss M. Kirschner: Physical Culture and Self-realisation. 8.15 P.M., Dr. Margaret Lowenfeld: Child's Play and Man's Work.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.

Sunday, June 16th.—10.30 A.M. (Newcastle General Hospital), Dr. G. F. Duggan: Surgical Cases.

UNIVERSITY OF BIRMINGHAM.

Tuesday, June 18th.—3.30 P.M. (General Hospital), Mr. Scott Mason: Diagnosis and Treatment of Carcinoma of the Colon.

Thursday.—4 P.M. (Medical Lecture Theatre, University). Prof. K. Douglas Wilkinson: Acute Rheumatism and its Results. (Last Ingleby lecture.)

Friday.—3.30 P.M. (Queen's Hospital), Mr. D. J. Evans: Diseases of the Nasal Sinuses.

Appointments

ALLIN, E. S., M.D., has been appointed Senior Resident Officer to the Royal Gwart Hospital, Newport, Mon.

BEATON, NEIL, M.B. Glasg., F.R.C.S. Edin., Resident Surgical Officer at the King George Hospital, Ilford.

BEATTIE, JOHN, M.D. Camb., F.R.C.S. Eng., M.C.O.G., Assistant Physician-Accoucheur to St. Bartholomew's Hospital.

BEHRMAN, SIMON, B.Sc., M.R.C.P. Lond.. Registrar to the National Hospital for Diseases of the Nervous System.

BIRD, J. D. H.. M.B. Lond., F.R.C.S. Eng., Resident Assistant Surgical Officer and Casualty Officer at the King George Hospital, Ilford.

FOY, J. W. H., M.R.C.S. Eng.. D.M.R.E., Senior Assistant Medical Officer to the Radiological Department of the Manchester Royal Infirmary.

GOVER, W., B.M. Oxon., Honorary Physician to the Royal East Sussex Hospital.

KREMER, MICHAEL, M.D., M.R.C.P. Lond., Assistant Registrar to the National Hospital for Diseases of the Nervous System.

LANGLEY, G. F.. M.B. Brist., F.R.C.S. Eng., Senior Resident Medical Officer at the Bristol General Hospital.

LAUNER, N., M.B. Manch., Medical Registrar to Ancoats Hospital, Manchester.

MILLAR, A. U., M.B. Camb., D.M.R.E., Junior Assistant Medical Officer to the Radiological Department of the Manchester Royal Infirmary.

SMITH, H. E., M.B. Aberd., Hon. Ophthalmic Surgeon to the Royal Aberdeen Hospital for Sick Children.

STERN, DAVID, M.B. Edin., Resident Medical Officer at the Royal Infirmary, Sunderland.

TAYLOR. E. FOLEY, M.B. Dubl.. D.M.R.E. Camb.. Assistant Radium Officer to the Cancer Hospital (Free), London.

THOMSON. W. A. R., M.D., Paterson Research Scholar and Chief Assistant in the Cardiac Department of the London Hospital.

UNSWORTH, S. V., M.B. Liverp., F.R.C.S. Eng., Visiting Surgeon for the Mill-road Infirmary, Liverpool.

Queen Charlotte's Maternity Hospital, London.—The following appointments are announced:—

HARRIS, B. P.. M.B. Camb., Senior Resident Medical Officer:
MACKENZIE, K. F., M.B. Dub., F.R.C.S. Irel., Assistant Resident Medical Officer:
ROGERS, KATHARINE C., M.R.C.S. Eng.. Resident Anæsthetist and District Resident Medical Officer: and
CANN. A. M. R., M.B. Lond., Resident Anæsthetist.

London County Council Hospital Staff.—The following appointments, promotions, and transfers are announced. A.M.O.(I.) and (II.)=Assistant Medical Officer, Grades I. and II.

THOMPSON, C. G. K., M.B. Edin.. A.M.O. (I.). Brook;
MCGRATH, W. S., M.B. Sydney, F.R.C.S. Eng., A.M.O. (I.), St. Giles';
MARR, J. A. S.. M.B. Cape Town, F.R.C.S. Eng., A.M.O. (I.). St. Nicholas';
HOARE, C. M., M.B. Lond., A.M.O. (I.), Fulham;
STONE, D.. M.R.C.S. Eng., A.M.O. (I.). Lambeth;
MACRAE, D. J., M.D., F.R.C.S. Edin., A.M.O. (I.), St. George-in-the-East;
FRAZER. T. A., M.D. Aberd., A.M.O. (II.). Archway;
SMITH, S., M.B. N.Z., A.M.O. (II.). Bethnal Green;
ROSS, A. G.. M.B. Belf., A.M.O. (II.), St. Andrew's;
DENNISON, F. R., M.D. Lond., D.P.H., A.M.O. (II.), Colindale;
FURST. H. C., B.Sc., L.R.C.P. Edin., A.M.O. (II.). Lambeth;
ARTHUR. J. B., M.B. Edin., A.M.O. (II.), Dulwich:
GREENFIELD. L., M.B., A.M.O. (II.). St. Luke's (Chelsea):
SHERRIFF, G. G., M.B. Edin., A.M.O. (II.). St. Stephen's:
BRADBURY, E., B.Chir. Camb., A.M.O. (II.), St. Mary, Islington;

Vacancies

For further information refer to the advertisement columns

Aberdeen P[illegible] Res. M.O.

Aylesbury, [illegible] *Hospital.*—Sen. Res. M.O. £200. [illegible] £150.

Barnsley County Borough.—Asst. M.O.H., &c. £500.

Barry U.D.C. Surgical Hospital.—H.S. At rate of £200.

Beckenham, Bethlem Hospital, Monks Orchard.—Res. H.P. At rate of £150.

Belfast Royal Maternity Hospital.—Res. H.S. for Rea Block (Isolation). Also Res. M.O. At rate of £50 and £26 respectively.

Birmingham, Maryhull Colony Certified Institution.—Jun. Asst. M.O. £350.

Birmingham, Salterly Grange Sanatorium, near Cheltenham.—Med. Supt. £750.

Birmingham University, Dept. of Industrial Hygiene and Medicine. Research Worker and Lecturer. £600.

Birmingham University, Faculty of Medicine.—Lecturer in Bacteriology and Asst. Bacteriologist in Public Health Laboratory. £400.
Blackburn Royal Infirmary.—Res. Surg. O. £250. H.S. £175. Also Cas. O. £150.
Bolton Royal Infirmary.—Two H.S.'s. Each £125. Also Hon. Physician for Diseases of the Skin. £100.
Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £120.
Bristol General Hospital.—Two H.P.'s, two H.S.'s, Res. Obstet. O. H.S. to Spec. Depts. Also Cas. H.S. Each at rate of £80.
Burnley, Municipal General Hospital.—Jun. Res. M.O. £150.
Buxton, Devonshire Royal Hospital.—H.P. Also Asst. H.P. At rate of £200 and £150 respectively.
Carshalton, Surrey, Queen Mary's Hospital for Children.—Asst. M.O. £350.
Chester Royal Infirmary.—H.S. At rate of £150.
Chesterfield and North Derbyshire Royal Hospital.—H.S. to Ear, Nose, and Throat and Eye Depts. At rate of £150.
Children's Hospital, Hampstead, N.W.—Asst. Ear, Nose and Throat Surgeon.
Derbyshire Hospital for Sick Children.—Res. H.S. At rate of £130.
Doncaster Royal Infirmary.—H.S. to Eye and Ear, Nose, and Throat Depts., Cas. H.S. Also H.S. Each £175.
Eastbourne. St. Mary's Municipal Hospital.—Res. H.S. £150.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Res. Obstet. Asst. At rate of £50.
Fulham Borough Council.—M.O.H. £1100.
Golden Square Throat, Nose, and Ear Hospital, W.—Hon. [illegible]
[illegible] *Hospital.*—H.S. £150.
[illegible] rth H.S. At rate of £150.
[illegible] *Association, 10, Mall-road, W.*—
Anæsthetist.
Hampstead General and North West London Hospital, Haverstock Hill, N.W.—H.S. At rate of £100.
Harrogate Royal Bath Hospital.—Res. M.O. £156.
Hastings, Royal East Sussex Hospital.—Jun. H.S. At rate of £150. Also Hon. Asst. Physician.
Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.P. At rate of £100. Also Asst. Physician.
King Edward VII Sanatorium, Midhurst.—First Asst. M.O. £500.
King's College Hospital.—Radium Registrar.
Leyton Borough.—Temp. Asst. M.O. 10 guineas per week.
Liverpool, David Lewis Northern Hospital.—Cas. O. £120. Also H.S. and H.P. Each £80.
Liverpool, Royal Infirmary.—Medical Tutor and Registrar. £140.
London Hospital, E.—First Asst. to Gynæcological and Obstetric Dept. £250.
London University.—External Examinerships. Chair of Dental Prosthetics at Guy's Hospital Med. School. £1000. Also University Readership in Anatomy. £550.
Macclesfield General Infirmary.—Second H.S. At rate of £150.
Manchester Ancoats Hospital.—H.S. At rate of £100.
Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.
Manchester Royal Infirmary.—Res Clin. Pathologist. £100.
Manchester Victoria Memorial Jewish Hospital, Cheetham.—Clin. Pathologist. At rate of £250.
Manor House Hospital, Golders Green, N.W.—Jun. M.O. £200.
Milnathort, Kinross-shire, Ochil Hills Sanatorium.—Asst. M.O. £250.
Newcastle-upon-Tyne, Royal Victoria Infirmary.—Morning List Anæsthetist. At rate of £250. Also Anæsthetists, 12s. 10*d*. each afternoon.
Newport, Isle of Wight County Mental Hospital.——H.P. At rate of 150 guineas.
New Zealand, General Hospital, Auckland.—Sen. Surg. O. Also Sen. Med. O. Each £650.
Preston, Sharoe Green Hospital.—Sen. and Jun. Res. M.O.'s. At rate of £200 and £100 respectively.
Preston and County of Lancaster Queen Victoria Royal Infirmary. Special H.S. At rate of £150.
Princess Elizabeth of York Hospital for Children, Shadwell, E.—H.P. and H.S. Each at rate of £125.
Princess Louise, Kensington Hospital for Children, St. Quintin-avenue, W.—H.S. At rate of £100.
Putney Hospital, Lower Common, S.W.—Jun. M.O. At rate of £100.
Reading, Royal Berkshire Hospital.—H.S. Also Cas. O. Each at rate of £125.
Royal Northern Hospital, Holloway, N.—H.P. and H.S. Each at rate of £70.
St. Giles Hospital, Brunswick-square, S.E.—Asst. M.O. £350.
St. Mary Abbots Hospital, Marloes-road, Kensington, W.—H.P. At rate of £120.
St. Pancras Hospital, N.W.—Asst. M.O. £250.
St. Thomas's Hospital Medical School.—Demonstrator in Physiology. £400.
Sheffield Roya [illegible] H.S.'s. One H.P. Aural H.S.
Ophth. H [illegible] at rate of £80. Also Clin.
Asst. to [illegible] 300.
Shrewsbury, I [illegible] —Two Res. H.S.'s. Each
at rate of £160.
[illegible] *neral Hospital.*—Jun. Res. M.O. £200.
[illegible] *Borough.*—Med. Supt. for Council's
[illegible] Hospitals. £750.
[illegible] *Hospital.*—H.S. to Orthopædic and
South London Hospital for Women, Clapham Common, S.W.—H.S. At rate of £100.
Stafford, Staffordshire General Infirmary.—H.P. and Cas. O. At rate of £150.
Stirling District Mental Hospital, Larbert.—Jun. Assist. M.O. £300.
Sunderland Children's Hospital.—H.S. £120.
Sutton and Cheam Hospital.—Asst. Res. M.O. At rate of £100.
Swansea Cefn Coed Hospital.—Asst. M.O. £350.
Swansea General and Eye Hospital.—H.S. At rate of £150.
Weston-super-Mare General Hospital.—Res. H.P. £150.
Wigan, Royal Albert Edward Infirmary and Dispensary.—Res. Med. and Surg. O. and Reg. £250. Also H.S. At rate of £150.
Willesden General Hospital, Harlesden-road, N.W.—Hon. Clin. Assts. for Out-Patient Dept.
Windsor, King Edward VII Hospital.—Three H.S.'s. Each at rate of £100.
Wolverhampton, Royal Hospital.—Res. H.S.'s to Special Depts. Also Asst. Res. M.O. Each at rate of £100. Also H.P. At rate of £125.
Worcester Royal Infirmary.—H.P. Also Jun. H.S. £160 and £120 respectively.
York City.—Asst. M.O.H. At rate of £350.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Hatfield, Hertfordshire.

Births, Marriages, and Deaths

BIRTHS

Donovan.—On June 7th, at a nursing home, Birmingham, the wife of Hugh Donovan, F.R.C.S. Eng., of a daughter.
Fish.—On May 29th, at Brentwood, the wife of R. Huxley Fish, M.B. Camb., M.R.C.P. Lond., of a son (Daniel).
Havard.—On June 9th, the wife of R. Emlyn Havard, D.M. Oxon., Oxford, of a son.
Lloyd.—On June 2nd, at Towyn, Merionethshire, the wife of J. H. Marshall Lloyd, M.B. Lond., of a son.
Mills.—On June 4th, the wife of J. Denholm Mills, B.M. Oxon., of Seaford, of a son.
Morgan.—On June 2nd, at Ashfield, Crickhowell, Breconshire, the wife of J. L. Morgan, B.Chir. Camb., of a daughter.
Turner.—On June 7th, at Devonshire-place, the wife of Ronald Turner, M.R.C.S. Eng., of a son.

MARRIAGES

Buxton—Bragg.—On June 1st, at St. Paul's Church, Portman-square, Kenneth Leonard Buxton, F.R.C.S. Eng., of North Mimms, Herts., to Agnes Josephine Bragg, daughter of the Rev. Dr. and Mrs. T. Bragg, of Christ Church, Lowestoft.
Craig—Garrett.—On June 1st, at St. Margaret's Church, Leiston, Daniel Mackinnon Craig, M.R.C.S. Eng., of Framlingham, Suffolk, to Phyllis Clifton, youngest daughter of Lieut.-Colonel and Mrs. F. Garrett, of Leiston, Suffolk.
[illegible] June 1st, at Holy Trinity Church,
[illegible] William S. Paterson, M.D. Glasg., of
[illegible] daughter of the late Mr. Christopher
[illegible] shbourne.
Reah—Roberts.—On June 5th, 1935, at St. Mary's Church, Conway, North Wales, Thomas Glen Reah, M.D., M.R.C.P., elder son of Mr. and Mrs. J. Carter Reah, of Stockton-on-Tees, to Ruth M. Roberts, youngest daughter of the late D. and Mrs. Roberts, of Conway, North Wales.
Rice—Slater.—On June 6th, at St. Michael's Church, Blackheath, Hugh D. C. Rice, M.R.C.S. Eng., to Kathleen Mary, third daughter of Mr. and Mrs. Harold Slater, of "Colynton," Orpington, Kent.
Stern—Gildard.—On June 4th, at St. Columba's, Pont-street, David Michael Stern, F.R.C.S. Eng., of Dollis Hill-lane, N.W., to Eileen Freya Macleod, second daughter of the late Mr. J. Graham Gildard, of Glasgow, and Mrs. Gildard, of Frognal, N.W.
Walker—Cassie.—On June 8, at St. Peter's Church, Bayswater, C. G. Walker, M.D. Aberd., Oxted, Surrey, to Barbara Bathea Cassie, Stanley-gardens, London.

DEATHS

Biggs.—On June 3rd, at Barnstaple, John Maundy Biggs, L.R.C.P. Lond., L.S.A., in his eightieth year.
Braithwaite.—On June 7th, at Brackley, the result of a motor accident, Norman Braithwaite, M.B. Durh., aged 41.
Goldie.—On June 4th, at Upper Wimpole-street, W., George James Goldie, L.D.S., L.R.C.P. Edin., formerly of Merrion-square West, Dublin.
Hickey.—On June 4th, at Plymouth, Major A. J. Hickey, M.C., M.R.C.S. Eng., R.A.M.C., of Kilkee, County Clare, I.F.S.
Home.—On June 9th, at Yew Tree-road, Southborough, Kent, William Edward Home, O.B.E., B.Sc., M.D. Edin., Fleet Surgeon, R.N., Retired, in his seventy-fifth year.
Morton.—On June 6th, at the Governor's House, Holloway Prison, N., John Hall Morton, M.D., T.C.D.
Roberts.—On June 9th, Charles Roberts, F.R.C.S. Eng., of Didsbury and Manchester, age 60.
Stokes.—On June 5th, John Stokes, M.A., M.D. Durh., of Sheffield, in his seventieth year.
Stuart-Low.—On June 5th, at The Homestead, Northwood, William Stuart-Low, F.R.C.S. Eng., of Wimpole-street, aged 77.
Swindale.—On June 9th, at Glebe-place, Chelsea, suddenly, Henry Vernon Swindale, M.R.C.S. Eng.
Tait.—On June 7th, at Handcross, Sussex, Henry Brewer Tait, F.R.C.S. Eng.
Wilson.—On June 3rd, at The Vicarage, Muker, Yorkshire, Horace Bagster Wilson, O.B.E., M.R.C.S. Eng., Vicar of Muker, aged 72 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

RADIOLOGY OF TUBERCULOSIS

At a meeting of the North Western Tuberculosis Society held in Liverpool on May 30th, Dr. J. V. Sparks (London) read a paper on radiology in the diagnosis and treatment of pulmonary tuberculosis. In his opinion a case that was difficult radiologically was also usually difficult clinically and pathologically. Errors of interpretation in X ray films were due to films being poor in quality or too few in number and to undue bias, caused by a knowledge of the clinical data. It was necessary to obtain a correct amount of detail and correct density of films. Accurate control over the various factors of exposure was important to produce a correct and comparative density. A high milliamperage and low kilovoltage were desirable and a minimum time of exposure. As low as 1/100th sec. was practicable with modern apparatus. The focus of the X ray tube should not be too broad—a 6 kw. tube was big enough. At the Brompton Hospital a condenser apparatus had lately been installed, giving exposures of 1/30th second, variations in kilovoltage after measurement of patients alone being necessary. With this apparatus stereoscopy was not possible. Dr. Sparks then referred to the position of the patient and pointed out the various disadvantages of the upright, prone, and supine positions. He preferred to have patients seated rather than standing, and spoke well of the prone position. In any case, it was important to get the scapulæ out of the way. Variations in kilovoltage were important factors, and conspicuous changes in the appearance of films followed differences as low as 2 kv. The radiological diagnosis of tuberculosis depended on a recognition of tubercle formation, not on mottling or cavities.

X ray films, said Dr. Sparks in conclusion, should be interpreted as reports at autopsies were made—that is to say, uninfluenced by clinical observations. Personally, he did not advocate screening as a routine diagnostic procedure and found little help from stereoscopy.

FOOD SUPPLIES

In the course of a Chadwick lecture delivered in London on June 6th, Sir John Russell, F.R.S., director of the Rothamsted Experimental Station, pointed out that human beings require a complex diet, including not simply the classical body-forming substances, the mineral substances, and the more recently discovered vitamins, but possibly also other substances. In the absence of full and precise chemical knowledge of foods and food requirements there was safety in a varied diet drawn from a variety of sources. By various devices the British farmers' share in the home market was now being pegged. At present this country produced about 15 per cent. of its wheat supply and about 40 per cent. of its other foods: the line could by suitable pegging be drawn elsewhere. In two directions further information was urgently needed. What were the relative advantages of fresh and of preserved or chilled foods as articles of diet? And on what principles in a world of manipulated markets should Great Britain select the sources from which to draw her foods?

SOME APPLICATIONS OF CHEMISTRY

The Chemistry Research Board, which in 1927 succeeded the Chemistry Coördinating Research Board and took over its research laboratory at Teddington, has issued its first report to the Committee of the Privy Council for Scientific and Industrial Research (H.M. Stationery Office. 1*s.* 6*d.*). The 94 pages are mostly taken up by a summary of the work of the laboratory from its beginning, written by the director, Prof. G. T. Morgan, who in March retired from the presidency of the Chemical Society. Most of the matter is of general rather than medical interest. Some of it, such as the work on base-exchange methods of water-softening and a summary of present knowledge of the causes of plumbo-solvency of drinking waters, has been referred to in our columns. A special feature of the equipment of the laboratory at Teddington is the very fine apparatus constructed and used there for studying reactions (mostly with catalysts) at high pressures including one autoclave still in the experimental stages for 3000 atmospheres at 200° C. and several for 200 atmospheres at 300–400° C. Many interesting syntheses, e.g., of methyl and ethyl alcohols from hydrogen and carbon monoxide, and acetic acid from methyl alcohol and carbon monoxide, have been effected in this way. Of more direct medical interest is the work on chemotherapy. Two new series of quinquivalent arsenical compounds have yielded promising results as trypanocides and 500 grammes of succinamido-methyl-amide-p-arsenic acid has been sent for clinical trial at the Liverpool School of Tropical Medicine and in Nigeria. Various other compounds have been tested against trypanosomiasis and malaria and for antiseptic properties by Profs. Warrington Yorke, D. Keilin and C. H. Browning respectively. The most promising results have been obtained in antisepsis: quaternary salts from *o*-, *m*- and *p*-aminophenyl-phenanthridines are moderately powerful antiseptics in peptone-water and in serum, whilst similar salts from 3-amino-9-methyl-phenanthridine are powerful antiseptics in serum especially against *B. coli* but are impotent in peptone-water. Other derivatives of this group have yielded promising results and attempts to synthesise new types continue. Search has been made for a non-metallic substance to replace vulcanite for denture purposes and for an adhesive material to be used as a dental lute and cement.

WOUNDS OF THE HEART

An unusual case of foreign body in the heart was quoted in our issue of March 30th (p. 745), and it may be of interest to describe two other cases of cardiac wounding lately reported from Rumania by J. Jiano (Rev. de Chir. de Bucarest, 1935, xxxvii., 567).

The first patient received a shell wound during the late war, and was operated on as an emergency three-quarters of an hour later. On admission to hospital the pulse was fairly good, and the area of cardiac dullness normal; there was a lacerated wound in the precordial area with comminution of the upper part of the sternum and corresponding ribs. The skin wound was excised, loose pieces of bone and metal being removed, and parts of the sternum and of several ribs were resected to expose the pericardial sac, which showed a wound in its upper part. This wound was enlarged, and several clots removed from the cavity of the sac. A small fragment of metal was then seen embedded in the wall of the right auricle. As it was impossible to determine whether or no it had penetrated the wall, a purse-string suture of linen thread was introduced around it, and drawn tight as the fragment was extracted. The *projectile* was wedge-shaped and about 5 mm. long. The pericardium was closed without drainage, and the outer wound was treated by the Carrel-Dakin method. The patient died five days later however from mediastinitis.

The second case was that of a youth 19 years old, who was admitted to hospital with a stab-wound in the precordium. He was unconscious on admission but quickly recovered, and as no abnormal signs could be detected it was concluded that the wound was superficial and he was discharged four days later. A fortnight afterwards, however, he began to have pain in the precordial and epigastric regions, increased by coughing and by taking food, but somewhat relieved by vomiting. He was readmitted to hospital as a case of pericarditis, with engorgement of the veins of the neck, greatly enlarged area of cardiac dullness, distant heart sounds, a precordial rub, a pulse-rate of 90, and generalised bronchitis. At operation, preliminary puncture of the pericardial sac yielded altered blood, and on turning back a flap of the chest wall, the sac was found to be enormously distended and to contain more than a litre of black, altered blood. The heart was almost completely covered with organised clot, and on removing this a wound 5 mm. long, which immediately began to bleed, came into view on the anterior wall of the right ventricle, close to the apex. The heart was grasped in the left hand and the wound closed in three layers with interrupted sutures of catgut. The pericardial sac was cleansed, and closed with drainage. The flap was sutured back into position. The patient died six days later from broncho-pneumonia, and at post-mortem it was found that the wound in the heart was healed.

Jiano points out that in early cases there may be little or nothing in the physical signs to indicate a wound of the heart. He emphasises the importance of keeping all cases of precordial trauma under observation, and of early resort to operation if a wound is suspected.

THE RED CROSS EMBLEM

BY the laws and usages of war the Red Cross flag is hoisted over medical establishments, but it must not be used to cover the transport of ammunition or non-medical stores; rifles must not be fired from a Red Cross tent and hospitals must not be used as observation points. The Geneva Convention of 1906 *for ameliorating the condition of the wounded and* sick of armies in the field was ratified by Britain with a reservation for Articles 23 and 27 which forbade the the use of the Red Cross emblem except to indicate a military medical service. In 1911 Parliament passed an Act to give effect to the Convention; it prohibited the use of the Red Cross emblem or of the words "Red Cross" in a trade or business or for any other purpose without the authority of the Army Council. Our reservation as to Articles 23 and 27 was withdrawn on July 7th 1914. Questions of the abuse of the Red Cross in war-time by combatant countries have been debated by international lawyers of high repute; there was, for instance, a controversial incident in the battle of Mukden in 1905 over which academic opinion has been divided. A more pacific instance has now to be recorded. A hundred years ago a hostelry at North Cray in Kent was named the Red Cross Tavern. Twenty-four years after the passing of the 1911 Act, the vigilance of the War Office has detected this as an infringment of the Geneva Convention. At the recent licensing sessions at Bromley the justices were asked to sanction the change of the name of these licensed premises from the Red Cross to the White Cross Tavern. The bench asked cautiously if the new title involved any latent contravention of the law. The applicant said he hoped it did not, but he could not guarantee what the next 24 years might bring forth.

AN ITALIAN REVIEW OF PREVENTIVE MEDICINE

IN terse and picturesque language a little Italian manual[1] covers the whole field of preventive medicine, explaining in the simplest manner, but with accuracy, the rationale of public health measures, as well as that of the old-fashioned rules of bodily health. It appears that even under the paternal government of Mussolini cooks still prepare salads with unwashed hands; tuberculous nursemaids kiss the baby; the bath in municipal houses is used for clothes, not bodies; the sun is shut out from the children in order to spare the carpets; and the author of a manual on preventive medicine finds it necessary to plead: "Why not buy a cheap vacuum-cleaner instead of a cheap radio—it is so much less disturbing to the neighbours!" It appears also that, though the six-year-olds of the Roman Campagna can recite: "Malaria is a parasitic disease, caused by a protozoa in the blood and transmitted by a mosquito, the anopheles," yet their parents still leave stagnant water behind their houses for these same mosquitoes to breed in. Dr. Pampana begins with the need for physical cleanliness, including the daily bath (h. and c.), not forgetting the perils of the bathroom, "the most dangerous room in the house" from such causes as the cold bath immediately after a meal, the enervating effect of the overheated bath, the poisonous fumes of geysers, and the slippery floor. He passes on to the preparation of foods, to the principles of inoculation against infectious diseases, the early diagnosis of cancer and of those hidden septic foci which are said to be responsible for "rheumatic" diseases. To attain these latter goals he advises annual overhaul by a doctor, in favour of which he quotes certain insurance statistics; but he does not omit a warning against introspection and fear, reminding us that the emotions induced by a study of our own pulses can be factors in keeping up a blood pressure we desire to reduce. There is an admirable chapter on sex and the prophylaxis of venereal diseases. Idleness and overwork are both classed as undesirable luxuries to be avoided, and the author stresses the value of the Britisher's "hobbies." Referring to the campaign against tuberculosis, he recommends the Italian system of insurance against this disease, which promises in a few years to render possible the treatment of every case under ideal conditions. He considers the isolation of contagious cases from the healthy members of their families an essential measure, and supplies the interesting table of precautions against the spread of tuberculosis, which has been issued to the Italian public. Dr. Pampana's precepts are fundamentally those of common sense.

SWIMMING-BATH DEVELOPMENT

LAST month the National Association of Bath Superintendents held its annual conference at Hastings where for many years there has been a large system of swimming and other baths on the sea front, recently remodelled on sound lines, besides a large open-air bath on the shore at St. Leonards. A paper read at the conference by Messrs. E. Copeland Snelgrove, H. C. Husband and A. H. Clark struck a bold line worthy of consideration. It is of no use, they suggest, connecting the idea of swimming baths with that of town and country planning unless and until a status is achieved by a minimum of hygienic safety and attractive conditions introduced by statute into swimming bath practice and location. The present indifference to bathing is due, they think, to their unpleasant atmosphere (unless of open-air type) to their inadequate sanitary accommodation and memories of still worse things, to the dangerous state of the surface water, and to their generally unhappy situations in sordid areas or adjacent to public houses. There is without question a strong case for making swimming baths attractive places of public resort and safeguarding bathers by regulations dealing with preliminary ablution, including perhaps a sterilising shower to render costumes innocuous, with the purity of the water and with proper dressing accommodation. Then, as the authors would like, baths might be provided on a pro-rata basis for population. The locality should be well chosen and licensed premises, if desired, included in the bath compound. This will cost money but at the present rate of increase of popularity the bath may become as profitable as the cinema. Some, however, will still prefer the quiet river or the less frequented parts of the sea shore.

LOUSY BUT LOYAL

ACROSS a small street in one of London's humbler quarters, gaily decorated with bunting, paper wreaths, and natural flowers to demonstrate the jubilee sentiments of the dwellers, there floated a large label bearing the above inscription. The story is vouched for by a medical eye-witness, and the humorous pathos of the label deserves this little publicity.

In reply to queries we give the following address: The Lord Kitchener Memorial Fund, 34, Norfolk-street, London, W.C.2. Information concerning the Kitchener scholarships will be found in THE LANCET of May 25th, p. 1229.

ADDRESSES AND ORIGINAL ARTICLES

UNDULANT FEVER IN SCOTLAND

By C. P. BEATTIE, M.B. Edin., D.P.H.
LECTURER IN BACTERIOLOGY, UNIVERSITY OF EDINBURGH

J. SMITH, M.D., D.Sc. Aberd., M.R.C.P. Lond., D.P.H.
LECTURER IN BACTERIOLOGY, UNIVERSITY OF ABERDEEN; BACTERIOLOGIST TO THE CITY AND COUNTY OF ABERDEEN; AND

W. J. TULLOCH, O.B.E., M.D. St. And., D.P.H.
PROFESSOR OF BACTERIOLOGY, UNIVERSITY OF ST. ANDREWS

SINCE the first case of undulant fever due to *Brucella abortus* in Scotland was reported in 1930,[1] a sufficient number of cases have been recorded for an attempt to be made to assess the epidemiological and clinical features of the disease.

We have collected for the Scottish Committee on Bovine Contagious Abortion, partly privately and partly through the Scottish Department of Health, records of 97 cases of undulant fever. This information was obtained by means of questionnaires sent to the doctor in charge of each case. We propose to analyse these records, but before doing so, we wish to review briefly the modes by which infection may be acquired, and to consider how they apply to Scotland.

Infection may be acquired through handling animals or meat products infected with brucella. In this mode of infection the organism is presumed to pass through abrasions in the skin. Hardy and his colleagues[2] have demonstrated in guinea-pigs, and Otero[3] in human volunteers, that it can readily do so.

Brucella infection is common among the livestock of this country. Priestley[4] states that in England no less than 20 per cent. of cattle and 5–15 per cent. of horses are infected. He found no evidence of infection among sheep or swine. Our own experience leads us to believe that the proportion of infected cattle in Scotland is equally great. It is not then surprising to find that the number of cases of undulant fever occurring among persons whose occupation involves the handling of animals or meat is out of proportion to their numerical representation in the population. Thus in our series of 97 cases, 14 were of this class. Ten were farm workers, 2 were butchers, 1 was a milkmaid, and 1 a blacksmith who gave a history of having shod a horse with a disease of its legs shortly before the onset of his illness. Unfortunately no bacteriological investigation was carried out on the horse.

Another particular case among our series was of a bacteriologist. He had worked with cultures of brucella, although not for some considerable time previous to the onset of his illness. But it is possible that his was a laboratory infection.

In Scotland, however, the majority of the population have no direct contact with animals. In their case infection is probably acquired through drinking infected milk, or, less likely, by eating infected butter or cheese. We have previously shown that in Edinburgh 19·8 per cent. of raw milk from single sources contained *Br. abortus*, while in the ordinary mixed retailed milk coming from several sources, the percentage was 34·9.[5] In Aberdeen 28·3 per cent. of raw milk contained *Br. abortus*.[6] Our experience agreed with that of other workers that pasteurisation by the holder method effectively kills the organism. There is thus ample opportunity for contracting infection with *Br. abortus* through the consumption of raw milk. Infection through eating butter or cheese is not probable. For the most part these foods are made with pasteurised milk and one of us, (J. S.)[7] failed to culture *Br. abortus* from 79 samples of butter, 39 samples of margarine, and 26 samples of cheese.

An inquiry into the amount of milk drunk by the patients in our series of cases showed that 18 drank one pint or more a day, 8 drank cream, 21 drank under one pint, while 15 took milk only in tea or coffee, or on puddings or porridge. One inexplicable case was of a patient who had no contact with animals and took milk only in tea or in puddings; then she used pasteurised milk.

We consider that the proportion of undulant fever patients who drink one pint or more of milk a day is much greater than the proportion of the whole population who drink this amount. Nor is it likely that one in twelve of the population drink cream. In an infected milk *Br. abortus* is found in greatest numbers in the cream. The 15 patients who took very little milk represent more fairly the average population.

Among the heavy milk drinkers were eight who used a milk diet for medical reasons. They included two patients suffering from gastric ulcer, one suffering from cirrhotic liver, one with indigestion, and a diabetic whose diet included much cream. For a fortnight shortly before the onset of his illness, one patient, not previously a heavy milk drinker, had been taking three to four pints a day. Two of the patients while at home drank nothing but pasteurised milk. Shortly before the onset of their illness they had been away from home and drank raw milk. It is possible, as Dalrymple-Champneys suggests,[8] that the regular consumption of *Br. abortus* infected milk produces an immunity.

In certain cases an inquiry was made into the infection with *Br. abortus* of the milk-supply from which patients obtained their milk. As a result bacteriological proof of the presence of the organism in the milk was obtained in 23 instances, and in 16 others contagious abortion was found to be present in the herd. In several instances two or more patients were found to obtain their milk from the same source.

Epidemiological Study

Number of cases reported by years.—From 1929 till 1931 there was an increase in the number of cases reported year by year. In the years 1932–33–34 the figures have been almost steady. The numbers reported in the various years were: 1929, 3; 1930, 10; 1931, 13; 1932, 24; 1933, 22; 1934, 24. The date of one patient's illness cannot be exactly determined.

Geographical distribution.—Twelve cases occurred in Edinburgh, 9 in Aberdeen, 5 in Glasgow, 4 in Dundee, 17 in Aberdeenshire, 11 in Fifeshire, 6 in Kincardinshire and in Banffshire, 5 in Angus and in Ross and Cromarty, 4 in Stirlingshire, 2 in Ayrshire and in Inverness-shire, and 1 in Moray, Perthshire, Dunbartonshire, Renfrewshire, Dumfriesshire, Roxburghshire, Berwickshire, East Lothian, and in the Stewartry of Kirkcudbright.

Sex incidence.—As in other countries the disease has been found to attack males predominantly. In our series there were 62 males (63·8 per cent.) and 35 females (36·2 per cent.). Hardy and his associates[9] have pointed out that in their series the preponderance of males was due to their engaging to a greater extent in occupations involving contact with animals. Of all their cases 77 per cent. were males and 23 per cent. females. When they excluded those having contact with livestock or carcasses they found the proportion was 51 per cent. males and 49 per cent. females. We have made a similar exclusion and find that males still predominate, the figures being: males 49 (59 per cent.) and females 34 (41 per cent.).

Age incidence.—This is shown graphically (Fig. 1). It will be seen that our results agree with those of observers in other countries in that the disease affects chiefly young adults.

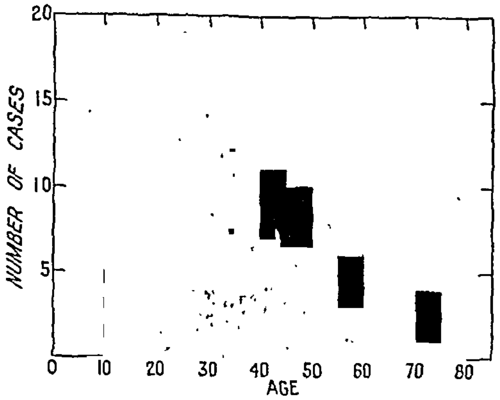

FIG. 1.—Age distribution.

Occupational incidence.—Apart from the large number of cases that occurred among those handling livestock or meat to whom we have already referred, the only notable feature under this heading was the relatively high proportion of doctors and nurses affected. There were four of each. We are not inclined to consider that this indicates that they run any special occupational risk, but rather that in their cases better facilities are available for diagnosis.

Duration of illness.—In 92 of the cases recorded the duration of illness was ascertained. It varied from 2 to 54 weeks, the average duration being 10 weeks. One patient, the report of whose case has not been used in computing the average duration of illness, has been ill for 108 weeks.

Case-mortality.—In the series there were 5 deaths.

One was of a patient suffering from disseminated sclerosis and was probably not due to undulant fever. Of the others, the first was of a young man, aged 29, whose death after 10 weeks' illness followed on a severe gastric hæmorrhage. This case has already been reported.[10] The second was of an elderly woman, aged 72, who was ill for approximately 44 weeks. About a month before her death she began to show signs of heart failure. The third was of a man, aged 68, who died after 44 weeks of illness. He was found to have pancreatitis, and from his pancreas *Br. abortus* was cultured (Case 2).

The fourth was of a man aged 32. His illness was acute with irregular bouts of fever. Night sweating, headache, and joint and muscle pains were pronounced symptoms. His liver and spleen were both much enlarged, and the presence of free fluid in his abdomen gave rise to the suspicion that he had a tuberculous infection. Laparotomy was therefore carried out. No signs of tuberculosis were present, but he was found to have marked cirrhosis of the liver. The abdomen was drained of free fluid and closed. A week later, seven weeks after the onset of his illness, the patient died. Culture of the free fluid from the abdomen failed to give a growth of *Br. abortus*. In view of the rapid onset of cirrhosis of the liver during an acute attack of undulant fever we feel justified in ascribing this patient's death to undulant fever.

If the patient suffering from disseminated sclerosis is omitted there are four deaths in our series giving a case-mortality of 4·1 per cent.

Bacteriological Investigation

Agglutination tests from patients.—In all cases an agglutination titre for *Br. abortus* of 1 : 100 or more was obtained with the patient's serum. In some cases it was much higher, the highest titre found being in a fatal case when it rose to 1 : 51,000. The titres were as follows:—

Titre.	Number.
1 : 100 – 1 : 199	7
1 : 200 – 1 : 399	7
1 : 400 – 1 : 799	10
1 : 800 – 1 : 1,599	13
1 : 1,600 – 1 : 3,199	21
1 : 3,200 – 1 : 6,399	17
1 : 6,400 – 1 : 12,799	12
1 : 12,800 – 1 : 25,599	6
1 : 25,600 – 1 : 51,000	1
1 : 51,000 –	1

As the agglutination tests were carried out in different laboratories with different antigens and different times and methods of incubation they are not strictly comparable. They demonstrate, however, a preponderance of reactions between the titres of 1 : 800 and 1 : 12,799.

In all cases the usual Widal reaction with *B. typhosus* and *B. paratyphosus* B antigens was also carried out. One patient gave an agglutination reaction with *B. paratyphosus* B antigen in dilution up to 1 : 400 and also with *Br. abortus* antigen in dilution up to 1 : 800. As her clinical condition was more suggestive of paratyphoid, she was considered to be suffering from that condition and is not included in the list. Also excluded is a child suffering from bacillary dysentery, whose serum agglutinated *Br. abortus* in dilutions up to 1 : 200.

Cultural tests from patients.—In some cases cultures of blood, urine, fæces, or organs were carried out. The results were as follows:—

	Cultures.	Positive and per cent.
Blood	51	12 (19·2)
Urine	11	1
Fæces	7	1
Pancreas	1	1
Ascitic fluid	1	0

In every instance the organism isolated was *Br. abortus*. There is no evidence of any other member of the genus brucella being present in Scotland.

Clinical Features

We present an analysis of the chief clinical features noted in our cases in the hope that thereby we may assist physicians in recognising the disease. We would, however, give a warning that the absence of any or most of the signs and symptoms recorded should not be taken to exclude the possibility of undulant fever. Few if any diseases are so varied in their manifestation and course. Hughes[11] writes "So variable are the symptoms and so uncertain is the duration and course of the fever that it is impossible to give a description to which all cases can be referred."

Nature of onset.—In 57·3 per cent. of the cases the onset was said to be insidious. Not atypica of the descriptions received were the following reports. (1) "I cannot say whether the patient developed undulant fever in January or February of this year. I know that from the end of last year till the beginning of this year she had been feeling out of sorts." (2) "Went to bed March 28th. Not well for a week or two before." (3) "Confined to bed on Sept. 8th out for fully a month prior to that date had complained of tiredness." (4) "For previous six weeks felt tired and disinterested in work and had loss of appetite."

Of all the cases 42·7 per cent. were said to have been of sudden onset. In only a few cases was detailed nformation received as to how sudden.

The onset of one patient's illness appears to be of xtreme rapidity, but symptoms of illness had been present previously. "She had not felt very well for ome days, and while at work she suddenly developed a evere pain in stomach and vomited. She went to bed but pain persisted, and shivering became worse. Was een about an hour later. She was in bed very collapsed and pale and in the middle of a severe rigor. The pain was referred to the epigastrium."

The percentage incidence of various signs and symptoms is given in Fig. 2.

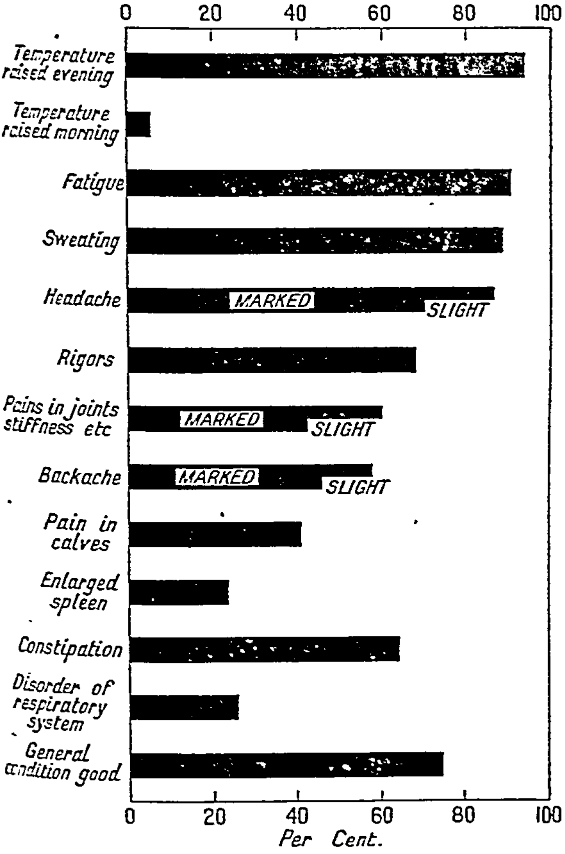

FIG. 2.—Percentage incidence of certain signs and symptoms.

Fever.—In every case fever was present. Generally this was found in the evening although in 6 per cent. of our cases the temperature was raised in the morning. Some of the temperature charts received showed an undulating curve with periods of about a week of high evening temperature followed by two or three days when the temperature was little raised. In others the temperature was raised every evening during the course of the illness. The temperature records received were, however, too few for any accurate estimate to be formed of the type of fever most commonly present.

Fatigue was almost always present and frequently was the most conspicuous symptom. Sometimes it was present all day, but more usually it was present in the afternoon.

Sweating was usually a marked feature. A common history was that the patient had to change his night clothes once or twice during the night.

Headache was commonly present. Often it was occipital but there was no one localisation. At times it was accompanied by pain in the back of the neck which was accentuated when the patient tried to turn or lift his head.

Rigors were noted in 68 per cent. of the cases. Generally they occurred in the afternoon. In a few cases they were reported to be severe, but more usually they consisted in a feeling of chilliness.

Backache, pain in joints, pain in calves, stiffness.—A large number of patients complained of these symptoms. The proportion of cases in which they occurred will be found in the Table. Arthritis was also frequently present. The joints affected were of the shoulder, elbow, hand, and knee.

Respiratory system.—The respiratory disturbances reported were, for the most part, indicative of slight congestion of the lungs. In only 3 cases was a cough reported to be present, and in 2 of these it was accompanied by the expectoration of muco-purulent sputum. One case was at first diagnosed as pleurisy owing to the presence of a severe pain in the side.

Gastro-intestinal system.—No specific inquiry was made as to the presence of abdominal pain. This is recorded in numerous reported cases, and in Hardy's [9] series its frequency was 30 per cent. In the reports we received information of its presence was volunteered in 7 cases. Sometimes it was accompanied by vomiting. Abdominal tenderness was also present in some instances. This was generally felt over the epigastric region, but in one case it was found over the gall-bladder, and in another over the liver. One patient was operated on for a subacute appendicitis. Simpson [12] points out the possibility of brucella infection presenting the characteristics of an acute abdominal condition. He records 94 cases in which cholecystectomy was performed and 26 in which appendectomy was performed. Gilbert and Coleman [13] have found brucella in the bile collected after cholecystectomy.

Loss of appetite was reported in some cases, and we believe it to be a common symptom. It was at times accompanied by a bad taste in the mouth. In a few cases the intestinal symptoms were the most prominent. We have already stated that one patient died after a severe gastric hæmorrhage. We also record two patients who died of the disease, one of whom had pancreatitis and the other cirrhosis of the liver.

Glandular system.—With three patients the onset of illness was accompanied by a swelling of the cervical glands. This suggests that the infection may have been through the tonsils. The work of Carpenter and Boak [14] who isolated the organism from 8 of 56 pairs of tonsils would support this view, but in Scotland after an examination of 100 pairs of tonsils Milne [15] did not find brucella.

Cutaneous system.—Eight of the patients had a skin rash. This was of a macular, sudaminous, or seborrhœic type, and in one case extended to the mucous membrane of the mouth and throat.

Cardiovascular system.—One patient, an elderly lady, died of heart failure. This was probably a sequel to her long illness. Another patient developed extrasystoles. Anæmia was frequently noted, and in four cases the medical attendant was struck by the yellow colour of the patient. In one case the blood pressure was markedly low, and in two epistaxis occurred.

Neurological system.—In a few cases irritability was very evident. More frequently the patient was greatly depressed. One patient who subsequently died of the disease was delirous at times. Insomnia was sometimes recorded. Diplopia was present in one instance due to paralysis of the muscles of the left eye.

Relapses occurred in 44 per cent. of the cases, at intervals of from five days to one month. In some cases three or more were reported. This experience differs from those of Hardy [9] and Simpson [12] in the United States of America, who both found relapses in only 15 per cent. of their cases.

General condition.—A notable feature of the disease is that frequently the condition of the patient looks much better than the physician would be led to expect from the height of the temperature. In 75 per cent. of our cases the general condition was good.

In some respects our results agree with those found in other countries, while in others they differ. We give a tabular comparison of the relative frequency of various symptoms and signs as found by Hardy [9] in the United States and by ourselves in Scotland.

	Hardy's results (per cent.).		Our results (per cent.).
Weakness	100	Fatigue	92
Sweating	84	—	88
Headache	62	—	87
Backache	48	—	59
Rigors	66	—	68
Palpable spleen	33	Enlarged spleen	24
Constipation	55	—	64
Relapses	15	—	44

Discussion

An analysis of the cases reported shows that those engaged in employment involving contact with animals or meat ran a special risk of contracting undulant fever. In this category were 14 of our 97 cases, a proportion much greater than that borne by those classes to the population as a whole.

The consumption of infected milk appeared to be responsible for the other cases. Many of them occurred among heavy consumers of milk. A deplorable feature was that 8 patients drank large quantities of milk for medical reasons. We would point out to practitioners that when they order patients to use a milk diet and do not specify that the milk should be pasteurised or boiled, they subject them to a definite risk of contracting undulant fever.

When the milk-supply was investigated, it was found in many cases that the milk contained *Br. abortus* or that the herd was infected with contagious abortion. That in some cases no evidence of infection of the milk-supply was obtained cannot be considered a valid argument against the spread of undulant fever by milk, for there must be few persons who do not take milk at times from another source than their home supply.

It is noteworthy that in the city of Glasgow, where 60 per cent. of the milk is pasteurised by the "holder" process, and 20 per cent. by the "flash" process, only 4 cases of undulant fever are known to have occurred. This accords with Dalrymple-Champneys's [8] findings in London. Out of 198 cases in England and Wales only 9 occurred in London, where over 90 per cent. of the milk is pasteurised. The experience in the United States has been the same. Few cases have been recorded from New York where the bulk of the milk is pasteurised. Even more definite evidence of the value of milk pasteurisation in preventing undulant fever is afforded by the experience of Simpson [16] in Dayton, Ohio. He reported 148 cases of undulant fever in this city and its neighbourhood and brought forward evidence to show that infection was milk borne. Three years ago a compulsory pasteurising order was brought into force. Since then not one case of undulant fever has originated in the city.

Undulant fever may seem not to be a disease of great importance. During the last three years the number of cases reported in Scotland has been a little over 20 each year. But a disease can hardly be considered unimportant which causes on an average 10 weeks of illness and is capable of producing an illness lasting for two years. Nor are we by any means certain that these 20 odd cases a year justly represent the incidence of undulant fever in Scotland. We have been struck by the fact that the reported cases surround centres where the bacteriological investigation of the disease is being carried out. It seems hardly likely that it should be less prevalent in other areas.

Further, from other countries reports are received of ambulatory forms of the disease. They formed a quarter of Hardy's series. We have found none, although in some cases the disease was mild. In not a few of our records it is stated that the patient felt unwell for a week or so before seeking medical attention. It appears not improbable that there are many persons whose undulant fever never goes further than the initial period of fever, lassitude, and aching.

We believe that if all cases of slight febrile illness without obvious cause were investigated a considerable number would prove to be cases of undulant fever. Hardy writes: "Probably no one thing should so influence a physician to consider brucella infection in differential diagnosis as a fever unexplained by positive physical signs." [9] We would ask physicians to submit blood samples from such patients to bacteriological laboratories in order that agglutination and cultural tests for brucella infection may be carried out.

Two Illustrative Cases

We give a brief report of two cases. The first provides a not unusual picture of the course of the disease and of the conditions on the farm supplying the milk. The second is a report of a fatal case. Another fatal case has already been recorded by Marr.[10]

CASE 1.—Girl, aged 15, training for domestic service; no contact with animals or carcasses; raw milk-supply. Illness began on Feb. 18th, 1934. Onset insidious: began with arthritis of right knee, which was accompanied by an evening rise of temperature. After a week the arthritis disappeared and the fever subsided for three days. Then arthritis of the right shoulder began, and the temperature was once more raised in the evening, reaching 100° F. Felt tired in the evening and perspired profusely at night. Appetite good, constipated. No headache or backache. Spleen and liver not enlarged. Had sudaminous and seborrhœic rash on her body, also dull red spots on her chest. General condition good. Illness lasted 20 weeks.

March 16th, 1934: [illegible] *Br. abortus* in dilutions up to 1:4[illegible] tested); no agglutination with *B.* [illegible] *phosus A or B.* March 27th: serum agglutinated *Br. abortus* in dilutions up to 1:3200. March 13th: *Br. abortus* cultured from blood. March 27th: whey taken from supplier's bottle of milk at patient's home agglutinated *Br. abortus* in dilutions up to 1:80. Subsequently *Br. abortus* was cultured from inoculated guinea-pigs.

On investigation of the cows on the farm supplying the milk 6 out of 29 showed definite evidence of *abortus* infection.

CASE 2.—A doctor, aged 68, practising in a country district, took ill about the second week of May, 1933, with indefinite symptoms, but later for four days from May 20th onwards was confined to bed, the evening temperature being in the region of 101° F. By the 24th he had so far recovered that he could attend to his work, but on June 1st he had a recurrence of fever for nine days. He went away for convalescence and returned on July 1st. On the 8th he had marked abdominal pain, and his evening temperature was 103° F. From this attack he recovered, but on August 1st he had again a recurrence of the fever with severe abdominal pain, headache, and delirium. Within five days the condition subsided and he felt fairly well again. On Dec. 6th, 1933, he again had an attack of abdominal and muscular pain. He remained fairly well until March 23rd, 1934, when he again had recurrence of abdominal pain and fever. He was admitted to a nursing-home, and examination now indicated a small palpable mass in the region of the pancreas. An exploratory operation was performed, and a small tumour was found associated with the pancreas. The tumour was aspirated and blood-stained fluid was obtained. The patient failed to make any headway, and died rather suddenly on March 24th.

Blood samples for the Widal reaction and culture were received from time to time. The first sample received on August 10th, 1933, failed to agglutinate any of the typhoid-paratyphoid group of organisms, but agglutinated *Br. abortus* to a dilution of 1 : 3200. On Sept. 17th the titre of the serum for *Br. abortus* had fallen to 1 : 8000, but when again taken during the course of the final illness on March 23rd, 1934, the titre had risen to 1 : 3200. Culture of the blood specimens under 10 per cent. CO_2 failed to show the presence of any organisms. When, however, the material obtained from the pancreatic abscess was cultured, a profuse growth of a CO_2-sensitive strain of *Br. abortus* was obtained.

Summary

(1) An account is given of 97 cases of undulant fever occurring in Scotland between 1929 and 1934.* (2) Of these, 14 were in persons having contact with animals or meat and may have been acquired by nature of their employment. In the remainder the consumption of infected milk appears to have been the cause of illness. Many of the patients had been heavy milk drinkers, sometimes on medical advice. (3) An analysis of the signs and symptoms of the disease shows their complexity. (4) The disease was most often found among young adults. (5) Males predominated. When those subjected to occupational risk were excluded the proportions were 59 per cent. males and 41 per cent. females. (6) The average duration of illness was 10 weeks. (7) The case-mortality was 4·1 per cent. (8) It appears likely that the milder forms of the disease pass unnoticed.

We express our thanks to the physicians who completed questionnaires regarding their patients and otherwise coöperated in this inquiry. We have made quotations from the information supplied to us by Dr. O. D. Jarvis, Dr. D. C. Glen, Dr. E. R. C. Walker, Dr. J. C. Mackay, Dr. J. S. Caldwell, and Dr. A. W. Hendry. Dr. R. Cruickshank reported to us five cases in which the bacteriological investigation was carried out in his laboratory. For a time the collection of records was in the hands of Dr. H. J. Gibson, to whom we are grateful. Finally we wish to acknowledge the assistance given by the Scottish Committee on Contagious Abortion and the Department of Health for Scotland.

One of us (C. P. B.) was assisted in the work by a grant from the Moray fund for research, Edinburgh University.

---

* Since this article was submitted for publication there have been received reports of 8 further cases of undulant fever, bringing the total number (since 1929) to 105.

THE HÆMOGLOBIN LEVEL

AMONG LONDON MOTHERS OF THE HOSPITAL CLASS

AND ITS PROBABLE BEARING ON SUSCEPTIBILITY TO INFECTION

By HELEN M. M. MACKAY, M.D., F.R.C.P. Lond.

PHYSICIAN TO THE QUEEN'S HOSPITAL FOR CHILDREN, HACKNEY, AND PHYSICIAN FOR DISEASES OF INFANTS, MOTHERS' HOSPITAL, CLAPTON; MEMBER OF THE STAFF OF THE MEDICAL RESEARCH COUNCIL

Assisted by LOREL GOODFELLOW

THE prevalence of anæmia due to iron deficiency among infants and young children has caused attention to be focused upon the hæmoglobin level in their mothers. In this paper particulars are given of the results of hæmoglobin estimations in three groups of women, a total of 368 persons. Some of the figures have already been published[1] but the results are further analysed here. The estimations were made with a Haldane hæmoglobinometer from blood obtained from a prick in the lobe of the ear. The standard used latterly was a Price-Jones-Haldane tube,[2] and figures obtained with an earlier hæmoglobinometer have been corrected to correspond with the Price-Jones-Haldane standard.[3]

A GROUP OF NURSING MOTHERS

The first group consists of 50 nursing mothers at different stages of lactation (from the first to the tenth month) whose blood was examined in 1930.[1] Their babies were attending the Mothers' Hospital infant welfare centre. Babies at this centre showed the usual nutritional anæmia when not treated with iron; those who were entirely breast-fed until seven months of age had an average hæmoglobin level at 11–12 months old of 72·5 per cent. (Price-Jones-Haldane standard), which, reckoning the infants' normal as 86 per cent. is 13·5 per cent. below normal. The economic status of the parents varied, but was on the whole fairly good. Some of the fathers were small shopkeepers employing a domestic servant; some were shop assistants or clerks; others were manual workers. Relatively few were unskilled casual labourers. The mothers' ages ranged from 18 to 42; 27 were primiparæ and 23 multiparæ, the latter with an average of 2·9 pregnancies each. The average hæmoglobin level of these women was 82·8 per cent. (Table I.), and in 58 per cent. of them it was below 85 per cent. There was very little difference between primiparæ and multiparæ; the former averaged 83·4 per cent., the latter 82·4 per cent. Taking Price-Jones's average of 98·26 per cent. for healthy women, these mothers averaged 15·5 per cent. below his normal; and on this basis the degree of was very evident. More frequently the patient was greatly depressed. One patient who subsequently died of the disease was delirous at times. Insomnia was sometimes recorded. Diplopia was present in one instance due to paralysis of the muscles of the left eye.

Relapses occurred in 44 per cent. of the cases, at intervals of from five days to one month. In some cases three or more were reported. This experience differs from those of Hardy[9] and Simpson[12] in the United States of America, who both found relapses in only 15 per cent. of their cases.

General condition.—A notable feature of the disease is that frequently the condition of the patient looks much better than the physician would be led to expect from the height of the temperature. In 75 per cent. of our cases the general condition was good.

In some respects our results agree with those found in other countries, while in others they differ. We give a tabular comparison of the relative frequency of various symptoms and signs as found by Hardy[9] in the United States and by ourselves in Scotland.

	Hardy's results (per cent.).		Our results (per cent.).
Weakness	100	Fatigue	92
Sweating	84	—	88
Headache	62	—	87
Backache	48	—	59
Rigors	66	—	68
Palpable spleen	33	Enlarged spleen	24
Constipation	55	—	64
Relapses	15	—	44

Discussion

An analysis of the cases reported shows that those engaged in employment involving contact with animals or meat ran a special risk of contracting undulant fever. In this category were 14 of our 97 cases, a proportion much greater than that borne by those classes to the population as a whole.

The consumption of infected milk appeared to be responsible for the other cases. Many of them occurred among heavy consumers of milk. A deplorable feature was that 8 patients drank large quantities of milk for medical reasons. We would point out to practitioners that when they order patients to use a milk diet and do not specify that the milk should be pasteurised or boiled, they subject them to a definite risk of contracting undulant fever.

When the milk-supply was investigated, it was found in many cases that the milk contained *Br. abortus* or that the herd was infected with contagious abortion. That in some cases no evidence of infection of the milk-supply was obtained cannot be considered a valid argument against the spread of undulant fever by milk, for there must be few persons who do not take milk at times from another source than their home supply.

It is noteworthy that in the city of Glasgow, where 60 per cent. of the milk is pasteurised by the "holder" process, and 20 per cent. by the "flash" process, only 4 cases of undulant fever are known to have occurred. This accords with Dalrymple-Champneys's[6] findings in London. Out of 198 cases in England and Wales only 9 occurred in London, where over 90 per cent. of the milk is pasteurised. The experience in the United States has been the same. Few cases have been recorded from New York where the bulk of the milk is pasteurised. Even more definite evidence of the value of milk pasteurisation in preventing undulant fever is afforded by the experience of Simpson[16] in Dayton, Ohio. He reported 148 cases of undulant fever in this city and its neighbourhood and brought forward evidence to show that infection was milk borne. Three years ago a compulsory pasteurising order was brought into force. Since then not one case of undulant fever has originated in the city.

Undulant fever may seem not to be a disease of great importance. During the last three years the number of cases reported in Scotland has been a little over 20 each year. But a disease can hardly be considered unimportant which causes on an average 10 weeks of illness and is capable of producing an illness lasting for two years. Nor are we by any means certain that these 20 odd cases a year justly represent the incidence of undulant fever in Scotland. We have been struck by the fact that the reported cases surround centres where the bacteriological investigation of the disease is being carried out. It seems hardly likely that it should be less prevalent in other areas.

Further, from other countries reports are received of ambulatory forms of the disease. They formed a quarter of Hardy's series. We have found none, although in some cases the disease was mild. In not a few of our records it is stated that the patient felt unwell for a week or so before seeking medical attention. It appears not improbable that there are many persons whose undulant fever never goes further than the initial period of fever, lassitude, and aching.

We believe that if all cases of slight febrile illness without obvious cause were investigated a considerable number would prove to be cases of undulant fever. Hardy writes: "Probably no one thing should so influence a physician to consider brucella infection in differential diagnosis as a fever unexplained by positive physical signs."[9] We would ask physicians to submit blood samples from such patients to bacteriological laboratories in order that agglutination and cultural tests for brucella infection may be carried out.

Two Illustrative Cases

We give a brief report of two cases. The first provides a not unusual picture of the course of the disease and of the conditions on the farm supplying the milk. The second is a report of a fatal case. Another fatal case has already been recorded by Marr.[10]

CASE 1.—Girl, aged 15, training for domestic service; no contact with animals or carcasses; raw milk-supply. Illness began on Feb. 18th, 1934. Onset insidious: began with arthritis of right knee, which was accompanied by an evening rise of temperature. After a week the arthritis disappeared and the fever subsided for three days. Then arthritis of the right shoulder began, and the temperature was once more raised in the evening, reaching 100° F. Felt tired in the evening and perspired profusely at night. Appetite good, constipated. No headache or backache. Spleen and liver not enlarged. Had sudaminous and seborrhœic rash on her body, also dull red spots on her chest. General condition good. Illness lasted 20 weeks.

March 16th, 1934: serum agglutinated *Br. abortus* in dilutions up to 1:480 (highest dilution tested); no agglutination with *B. typhosus* or *B. paratyphosus* A or B. March 27th: serum agglutinated *Br. abortus* in dilutions up to 1:3200. March 13th: *Br. abortus* cultured from blood. March 27th: whey taken from supplier's bottle of milk at patient's home agglutinated *Br. abortus* in dilutions up to 1:80. Subsequently *Br. abortus* was cultured from inoculated guinea-pigs.

On investigation of the cows on the farm supplying the milk 6 out of 29 showed definite evidence of *abortus* infection.

CASE 2.—A doctor, aged 68, practising in a country district, took ill about the second week of May, 1933, with indefinite symptoms, but later for four days from May 20th onwards was confined to bed, the evening temperature being in the region of 101° F. By the 24th he had so far recovered that he could attend to his work, but on June 1st he had a recurrence of fever for nine days. He went away for convalescence and returned on July 1st. On the 8th he had marked abdominal pain, and his evening temperature was 103° F. From this attack he recovered, but on August 1st he had again a recurrence of the fever with severe abdominal pain, headache, and delirium. Within five days the condition subsided and he felt fairly well again. On Dec. 6th, 1933, he again had an attack of abdominal and muscular pain. He remained fairly well until March 23rd, 1934, when he again had recurrence of abdominal pain and fever. He was admitted to a nursing-home, and examination now indicated a small palpable mass in the region of the pancreas. An exploratory operation was performed, and a small tumour was found associated with the pancreas. The tumour was aspirated and blood-stained fluid was obtained. The patient failed to make any headway, and died rather suddenly on March 24th.

Blood samples for the Widal reaction and culture were received from time to time. The first sample received on August 10th, 1933, failed to agglutinate any of the typhoid-paratyphoid group of organisms, but agglutinated *Br. abortus* to a dilution of 1 : 3200. On Sept. 17th the titre of the serum for *Br. abortus* had fallen to 1 : 8000, but when again taken during the course of the final illness on March 23rd, 1934, the titre had risen to 1 : 3200. Culture of the blood specimens under 10 per cent. CO_2 failed to show the presence of any organisms. When, however, the material obtained from the pancreatic abscess was cultured, a profuse growth of a CO_2-sensitive strain of *Br. abortus* was obtained.

Summary

(1) An account is given of 97 cases of undulant fever occurring in Scotland between 1929 and 1934.* (2) Of these, 14 were in persons having contact with animals or meat and may have been acquired by nature of their employment. In the remainder the consumption of infected milk appears to have been the cause of illness. Many of the patients had been heavy milk drinkers, sometimes on medical advice. (3) An analysis of the signs and symptoms of the disease shows their complexity. (4) The disease was most often found among young adults. (5) Males predominated. When those subjected to occupational risk were excluded the proportions were 59 per cent. males and 41 per cent. females. (6) The average duration of illness was 10 weeks. (7) The case-mortality was 4·1 per cent. (8) It appears likely that the milder forms of the disease pass unnoticed.

We express our thanks to the physicians who completed questionnaires regarding their patients and otherwise coöperated in this inquiry. We have made quotations from the information supplied to us by Dr. O. D. Jarvis, Dr. D. C. Glen, Dr. E. R. C. Walker, Dr. J. C. Mackay, Dr. J. S. Caldwell, and Dr. A. W. Hendry. Dr. R. Cruickshank reported to us five cases in which the bacteriological investigation was carried out in his laboratory. For a time the collection of records was in the hands of Dr. H. J. Gibson, to whom we are grateful. Finally we wish to acknowledge the assistance given by the Scottish Committee on Contagious Abortion and the Department of Health for Scotland.

One of us (C. P. B.) was assisted in the work by a grant from the Moray fund for research, Edinburgh University.

* Since this article was submitted for publication there have been received reports of 8 further cases of undulant fever, bringing the total number (since 1929) to 105.

THE HÆMOGLOBIN LEVEL
AMONG LONDON MOTHERS OF THE HOSPITAL CLASS
AND ITS PROBABLE BEARING ON SUSCEPTIBILITY TO INFECTION

By HELEN M. M. MACKAY, M.D., F.R.C.P. Lond.
PHYSICIAN TO THE QUEEN'S HOSPITAL FOR CHILDREN, HACKNEY, AND PHYSICIAN FOR DISEASES OF INFANTS, MOTHERS' HOSPITAL, CLAPTON; MEMBER OF THE STAFF OF THE MEDICAL RESEARCH COUNCIL

Assisted by LOREL GOODFELLOW

THE prevalence of anæmia due to iron deficiency among infants and young children has caused attention to be focused upon the hæmoglobin level in their mothers. In this paper particulars are given of the results of hæmoglobin estimations in three groups of women, a total of 368 persons. Some of the figures have already been published[1] but the results are further analysed here. The estimations were made with a Haldane hæmoglobinometer from blood obtained from a prick in the lobe of the ear. The standard used latterly was a Price-Jones-Haldane tube,[2] and figures obtained with an earlier hæmoglobinometer have been corrected to correspond with the Price-Jones-Haldane standard.[3]

A GROUP OF NURSING MOTHERS

The first group consists of 50 nursing mothers at different stages of lactation (from the first to the tenth month) whose blood was examined in 1930.[1] Their babies were attending the Mothers' Hospital infant welfare centre. Babies at this centre showed the usual nutritional anæmia when not treated with iron; those who were entirely breast-fed until seven months of age had an average hæmoglobin level at 11–12 months old of 72·5 per cent. (Price-Jones-Haldane standard), which, reckoning the infants' normal as 86 per cent. is 13·5 per cent. below normal. The economic status of the parents varied, but was on the whole fairly good. Some of the fathers were small shopkeepers employing a domestic servant; some were shop assistants or clerks; others were manual workers. Relatively few were unskilled casual labourers. The mothers' ages ranged from 18 to 42; 27 were primiparæ and 23 multiparæ, the latter with an average of 2·9 pregnancies each. The average hæmoglobin level of these women was 82·8 per cent. (Table I.), and in 58 per cent. of them it was below 85 per cent. There was very little difference between primiparæ and multiparæ; the former averaged 83·4 per cent., the latter 82·4 per cent. Taking Price-Jones's average of 98·26 per cent. for healthy women, these mothers averaged 15·5 per cent. below his normal; and on this basis the degree of anæmia among them was very similar to the degree of anæmia among twelve-month-old babies with a good breast-feeding history attending this clinic.

A GROUP OF PREGNANT WOMEN AND GIRLS

The second group consisted of 109 pregnant women and girls in homes for unmarried mothers. They came in at different stages of pregnancy, often in the last month, and their previous social circumstances varied greatly. Nearly all were primiparæ, and they were for the most part young; 38 were under 21 years of age and only 6 were 31 years or over—their ages ranged from 14 to 40 years. The hæmoglobin estimations were usually made at 1–2 weeks after admission. Their babies also showed nutritional anæmia. The average hæmoglobin level of the mothers was 83·5 per cent.—i.e., within 1 per cent. of the average of the group of nursing mothers already considered (Table I.). Approximately 60 per cent. of the group had a hæmoglobin level below 85 per cent., which is about the same proportion as among the nursing mothers.

A GROUP OF LONDON MOTHERS AT A CHILDREN'S HOSPITAL

The third group examined consisted of 209 women who had brought children to the out-patient department of the Queen's Hospital for Children, where most of our work on nutritional anæmia in babies has been done. This being a children's hospital only, none of the women attended as patients. They had all borne children. They varied in age from young mothers of 21 attending with a first child, to a grandmother of 61 years. The number of pregnancies through which each woman had passed varied from one to sixteen; 30 women had had eight or more. The time that had elapsed since the last confinement might be short or long, from under one month to thirty years. The economic status of the mothers was, on the whole, considerably worse than that of the nursing mothers attending the Mothers' Hospital. The fathers were for the most part manual workers, and some were out of work. On the other hand, a few were small shopkeepers and in more comfortable circumstances. Nevertheless the average hæmoglobin level of the mothers was slightly higher, namely, 87·2 per cent. as compared with 82·8 per cent. for the nursing mothers at the maternity hospital; of the total approximately 32 per cent. of women had a hæmoglobin level of under 85 per cent. (Table I.). The slightly lower hæmoglobin level of the nursing mothers cannot apparently be attributed to their more recent confinements, for if we select from the group at the Queen's Hospital all those who had been confined within ten months of the date of estimation we have a sub-group of 39 mothers with an average hæmoglobin level of 88·5 per cent.—i.e., a figure closely approximating to the average for the whole group. However, most of these 39 mothers who came to the Queen's Hospital were not breast-feeding their babies, and it is possible that the extra drain of lactation might bring about this difference in hæmoglobin level. Whether or not multiple pregnancies increase the tendency to anæmia is not brought out in these figures; 37 mothers who had been pregnant once only showed an average of 88·2 per cent. hæmoglobin, and 30 mothers, each of whom had been pregnant eight times or more (an average of 10·2 pregnancies each), were only about 3 per cent. lower—i.e., they had an average of 85·0 per cent. hæmoglobin. This comparison, however, does not settle the point, for in order to judge the effect of multiple pregnancies, the hæmoglobin estimation should have been made in every case either during pregnancy or alternatively shortly after confinement; whereas in our cases the estimation was often years after the last confinement. Nor was there much change in the average hæmoglobin level with increasing age (Table II.). The maximum difference between the average for the different age-groups is less than 4 per cent.

THE DEGREE OF ANÆMIA IN THESE GROUPS OF WOMEN AS COMPARED WITH THAT IN LONDON BABIES

Price-Jones [2] has published hæmoglobin figures for healthy women (Table I.). His estimations were made on women students and hospital nurses. Since our earlier standard has been corrected by his,[3] our figures should be comparable. His average was 98·26 per cent., the highest values obtained being 110 per cent., and the lowest 90 per cent. If, then, we call 90 per cent. the lower limit of normal, then those who reached normal in our groups numbered only 14 per cent. (nursing mothers), 26 per cent. (pregnant women), and 40 per cent. (children's hospital mothers); or 32 per cent. for the three groups combined (Table I.). Again, compared with his average, our groups were lower by 15·5, 14·8, and 11·1 per cent. respectively, and the three groups combined averaged 12·8 per cent., lower.

Is this likely to entail any serious defect in health in these women? By analogy with infants, it would certainly seem so. In two groups of artificially fed infants, one set getting iron therapy and the other acting as controls, the difference in hæmoglobin level at six months old was about 7 per cent., and by twelve months old had increased to about 13 per cent. (corrected figures, Price-Jones-Haldane standard).[3] With this difference in average hæmoglobin level the morbidity-rate of the control group of babies was approximately double that of the iron group.[1] If we call the normal during the second half year of life 86 per cent., then the controls at six months old were 14 per cent. and at twelve months old 16 per cent. below normal. Hence we may say that in infants an anæmia comparable in grade to that existing among these mothers doubled the morbidity-rate. It therefore seems reasonable to expect that the grade of anæmia existing among these mothers was sufficient to greatly increase their susceptibility to infection.

A COMPARISON OF OUR FIGURES WITH THOSE OBTAINED IN ABERDEEN AND ELSEWHERE

Anæmia among women is evidently common also in America. Brooke-Bland and Goldstein[4] in the United States state that about 50 per cent. of 200 maternity ward patients, whom they examined, were anæmic by their standard—i.e., had less than 3·5 million red cells per c.mm. Galloway[5] has published figures for the hæmoglobin values during pregnancy and afterwards of 222 private patients in Chicago, observed systematically. His estimations were made with a Sahli hæmoglobinometer, so that his values are not strictly comparable with ours. But his findings establish the fact that anæmia was very common among these private patients, for 65 per cent. of them showed at some time under 65 per cent. hæmoglobin.

A comparison of our figures for London mothers with those published from Aberdeen by Davidson and his colleagues[6] is of interest (Table I.). These workers also used the Price-Jones-Haldane hæmoglobinometer. The Aberdeen figures were obtained from the poorest class of the community. The women examined came as escorts for patients to the Aberdeen dispensary, an institution for those not eligible for medical attention under the panel system and unable to pay for medical help. The wage-earner of the family was *usually* unemployed. Hence these women came from a poorer stratum of society than most of our cases. If our London figures are combined, we find that approximately 44 per cent. of women had a hæmoglobin level under 85 per cent., whereas of the Aberdeen women about 47 per cent. were below this level. But what is more striking is that many more of the Aberdeen women were markedly anæmic; of our cases, 3·3 per cent. had less than 70 per cent. hæmoglobin as compared with about 14 per cent. of the Aberdeen cases.

IRON DEFICIENCY AND ACHLORHYDRIA IN MOTHER AND CHILD

Is this anæmia primarily due to iron deficiency? The Aberdeen workers bring forward evidence that it is.[6] They show that the iron in the diet of these families was low and hold that for the women it is often inadequate to meet the demands resulting from menstruation, pregnancy, and lactation. They show also the good response to iron treatment in 20 of the most anæmic cases. If our sample figures are representative of the hæmoglobin values of London working-class mothers (and more information is certainly desirable), we suggest that the majority show some degree of iron deficiency. How far dietetic deficiency in relation to the needs of the period of child-bearing is directly responsible, and what share of the responsibility for anæmia is due to achlorhydria or hypochlorhydria and consequent deficient absorption, still requires to be settled. The Aberdeen workers carried out test-meals on 28 women with hæmoglobin levels under 70 per cent. and 9 women with over 80 per cent. hæmoglobin, and found that 25 of the first group and one of the second group suffered from achlorhydria or hypochlorhydria. A similar incidence of hypochlorhydria and achlorhydria has been demonstrated by Davies and Shelley[7] among anæmic women either pregnant or recently confined. In their series of 26 anæmic women, attending a London hospital, 23 had deficient or absent hydrochloric acid secretion.

Achlorhydria will undoubtedly increase the tendency to anæmia, but may achlorhydria be itself the result of iron deficiency? The very interesting facts reported by Hawksley, Lightwood, and Bailey[8] concerning achlorhydria in babies and young children with iron-deficiency anæmia may have an important bearing on this point. In 12 out of 13 anæmic children examined by them, fractional test-meals revealed achlorhydria, and in 3 cases examined a year or more after treatment the achlorhydria still persisted. Is the achlorhydria due to the anæmia? If so, is nutritional anæmia in infancy a causal factor in the achlorhydria of adult life; and hence does it predispose to the iron-deficiency anæmia common among women? All this is hypothesis and more facts are required before it is possible to arrive at any conclusion.

Again, Strauss[9] has established the fact that iron deficiency in the pregnant woman causes anæmia in her offspring. So the treatment of pregnant women with iron in adequate doses and for a sufficient period would probably do much to lessen the incidence of anæmia among their babies—though we would urge that direct treatment of the baby should certainly not be neglected. It must be remembered that treatment of a nursing mother with iron does not apparently increase the iron available in her milk.

In human nutrition we are apt to take short views. Work with laboratory animals indicates the need of much longer views. In anæmia we see the effects of breaking a dietetic commandment visited on the second generation. Fortunately the remedy is simple.

SUMMARY

The average hæmoglobin level in 368 women of the hospital class—pregnant women or mothers—was 85·5 per cent. as estimated with the Price-Jones-Haldane hæmoglobinometer. As compared with Price-Jones's average figure for healthy women (98·26 per cent.) they were 13·7 per cent. lower, and of the total number less than a third had a hæmoglobin level of 90 per cent. or over; 90 per cent. being the lowest value among Price-Jones's series of healthy women. The degree of anæmia among the women was of a similar order to that existing among babies of six to twelve months old of the same social class. This anæmia of babies is sufficient to double their morbidity-rate. By analogy it is probable that anæmia is an important factor in lowering resistance to infection among women. The inter-relationship of iron deficiency in mother and child is discussed. Routine iron therapy of expectant mothers and of babies is urged.

THE INFLUENCE OF LARGE DOSES OF POTASSIUM CHLORIDE ON MYASTHENIA GRAVIS

By L. P. E. Laurent, M.D., M.R.C.P. Lond.
MEDICAL REGISTRAR, UNIVERSITY COLLEGE HOSPITAL, LONDON: AND

W. W. Walther, M.B. Lond.
GENERAL ASSISTANT IN THE DEPARTMENT OF CLINICAL PATHOLOGY, UNIVERSITY COLLEGE HOSPITAL

THE action of eserine, and of its analogue Prostigmin, in the relief of myasthenic symptoms (recently described by Mary Walker [1] [2] and confirmed by Pritchard[3] and Laurent[4]) has not yet received a wholly adequate explanation. The suggestion that eserine acts by delaying the destruction of acetylcholine by choline esterase at the motor nerve-ending seems the only workable hypothesis at present. Any substance known to facilitate the production or the utilisation of acetylcholine might therefore be expected to exercise a favourable influence on myasthenia.

Feldberg and Vartiainen,[5] in the course of experiments on the superior cervical ganglion of the cat, found that the addition of potassium chloride to the perfusing solution stimulated the ganglion cells. They also found that a dose of potassium chloride not large enough to do so directly, "raised the excitability of the ganglion cells to preganglionic stimuli, to acetylcholine and to other chemical stimulants." The enhancement of the stimulating effect of acetylcholine by potassium ions was found to be "of the order of 50 per cent." Further, they found that eserine "perfused through the ganglion in weak concentration (e.g., 1 in 10^6) strongly sensitises the ganglion cells to injections of acetylcholine, lowering the threshold dose 8 to 20 times. It has a weak, non-specific sensitising action, lowering the threshold by one-third to one-half for other substances." The latter include potassium ions.

In view of these findings we decided to investigate the possible influence of potassium chloride, in doses large enough to raise the blood potassium significantly, on cases of myasthenia.

In a preliminary investigation, using a modified technique, we determined the level of potassium in the blood plasma of 10 normal subjects and of 6 myasthenics. Our early results suggested that there might be a significant lowering of the plasma potassium in myasthenia. Repeated investigations on the same subjects, however, showed us that this was not so. One of the misleading factors was that the potassium level rises 2 or 3 mg. per 100 c.cm. after a meal; another that older subjects gave higher results, and all our myasthenics were young. Further, the 2 myasthenics who gave the lowest readings of all had such difficulty in swallowing that they were on a diet deficient in meat and vegetables, the two chief sources of potassium.

Method of potassium estimation.—Clear, non-hæmolised serum or plasma is deproteinised by means of tungstic acid (Folin and Wu), and the clear supernatant fluid is treated with nearly saturated sodium cobaltinitrite solution to precipitate the potassium as sodium potassium cobaltinitrite. This precipitate is washed with distilled water and a solution of metaphenylenediamine hydrochloride is added and the precipitate allowed to dissolve in this acid solution in the boiling water bath. A yellow colour is produced varying in intensity with the concentration of nitrite. This colour is compared with the colour produced by a standard potassium solution similarly treated, in a colorimeter.

This method is open to the objection that the colour produced by the metaphenylenediamine hydrochloride does not bear a linear relation to the concentration of nitrite, but this difficulty is easily overcome by using several standards representing different quantities of potassium. The advantages of the method are speed, simplicity, and sensitiveness, a perfectly adequate colour being produced by quantities as low as 0·2 c.cm. of plasma, provided a micro-colorimeter is used.

The error of this method is not more than ± 3 per cent.; results have been verified repeatedly by the permanganate and oxalic acid titration method of Kramer and Tisdall, and all the estimations have been carried out in duplicate.

The 10 normal subjects gave the following results expressed in mg. per 100 c.cm.:—

21·4, 17·5, 22·5, 15·2, 15·2, 15·9, 15·8, 15·8, 17·0, 18·0,

and the six myasthenics the following:—

15·7, 16·4 later 13·8, 15·2 later 15·8, 14·2, 15·8, 15·2.

Although the results in cases of myasthenia have always been rather low, we do not feel inclined to attach much importance to this, since a few of the normals have been equally low.

THERAPEUTIC RESULTS

Three patients with myasthenia were given 2 grammes potassium chloride orally five times a day, each dose being dissolved in half a tumblerful of water. They all claimed some subjective improvement, starting half an hour after each dose and passing off in the course of the next hour. Objectively we observed some slight diminution in ptosis, a little improvement in the range of ocular movement and increases of from 3 to 5 lb. in the power of the grasp. We considered this result encouraging, but by no means convincing. We then decided to try large single doses in the hope of obtaining a more clear-cut improvement. The accompanying photographs illustrate the effect of a dose of 12 g. given in a tumblerful of water. Before treatment the patient has well-marked bilateral ptosis although she is making a maximum effort to open her eyes. Her best effort at showing her teeth only reveals the upper incisors, and there is no trace of a nasolabial fold. The second photograph, taken under similar circumstances 45 minutes after potassium chloride, shows that the ptosis has almost completely disappeared. Retraction of the lips is improved, so that the canines are clearly visible, and the nasolabial fold is evident.

The 5 patients who have received single large doses have all shown results of a similar order. Ptosis, external ocular movements and facial appearance have always been improved to a greater extent than the limbs, although the recording dynamometer has shown constant increase in the power of the grasp of 3–15 lb. according to the case. Generally speaking, the cases with the greatest initial weakness have given the best response. One patient in particular, who was so weak that she could not hold the dynamometer, recorded a grasp of 10–15 lb. on every occasion after a large dose of potassium chloride.

In 2 cases we have taken the opportunity of

estimating the plasma potassium before and an hour after the ingestion of 12 g. of potassium chloride. A considerable rise took place in each case. The preliminary figures were 14·7 and 15·2 mg. per 100 c.cm., and they increased to 22·6 and 27·4 respectively.

Six patients with myasthenia have taken the salt daily for the past two months. Individual doses have varied from 4 to 6 g. and these have been taken six times a day. The largest total given in one day has been 40 g. This treatment has proved a valuable adjunct to prostigmin. Several of the patients complained that after the effect of prostigmin had worn off, they felt somewhat tired and listless. They have found that a dose of potassium chloride taken before the action of prostigmin has ended, relieves the feeling of exhaustion and to some extent prolongs the improvement brought about by this drug.

FIG. 1

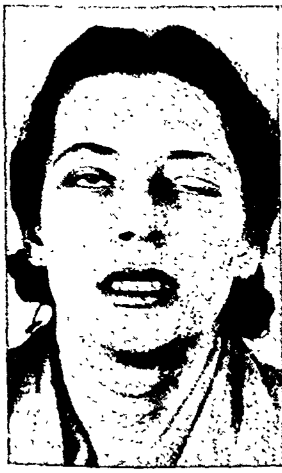

FIG. 2

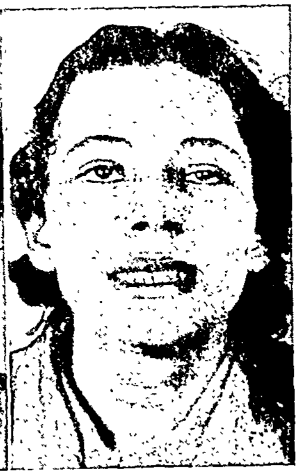

FIG. 1.—Before administration of potassium chloride. The patient is doing her best to open her eyes and clench her teeth.

FIG. 2.—Three-quarters of an hour after 12 g. potassium chloride. Similar efforts give better results.

Diuresis, of course, occurs constantly after each dose of the potassium salt. The only unpleasant symptom has been a mild diarrhœa which develops only from time to time in the course of prolonged administration. This can easily be controlled by drachm doses of bismuth carbonate. Nausea has followed the larger doses, but has not troubled the patients when smaller doses were being taken regularly.

The results obtained with the largest doses of potassium chloride tolerated by the patients are still somewhat short of the effect of 0·5 mg. prostigmin given by injection. This was to be expected if the action of potassium is the same as that of eserine—namely, to potentiate acetyl choline. Feldberg and Vartiainen[5] had found that eserine increased the effectiveness of acetylcholine 8 to 20 times, while potassium chloride only increased it by about 50 per cent. Eserine is, therefore, from 16 to 40 times more potent than potassium in this respect. The diuretic action of potassium salts no doubt accounts for the fact that the improvement which follows its administration never lasts more than two hours even after the largest dose.

It was not possible to demonstrate any increase in the potency of prostigmin when potassium was given simultaneously.

SUMMARY

(1) Potassium chloride given in large doses (10–12 g.) by mouth gives a demonstrable improvement in myasthenia. (2) In small repeated doses it is a useful adjuvant to prostigmin. (3) The theoretical considerations which led to these experiments are described and discussed.

We are grateful to Dr. F. M. R. Walshe and Dr. E. A. Blake Pritchard for access to some of their cases.

CLEFT PALATE

BY W. E. M. WARDILL, M.B. Durh., F.R.C.S. Eng.

ASSISTANT SURGEON TO THE ROYAL VICTORIA INFIRMARY, AND SURGEON TO THE BABIES' HOSPITAL, NEWCASTLE-UPON-TYNE

THE question of how to deal with a cleft palate, especially when it is associated with a hare-lip, is one which arises every now and then in practice, and draws one up with a shock. Hare-lip by itself is a problem only of cosmetics, but cleft palate involves also a possibility of malnutrition and later of defective speech. As regards the former, suffice it to say that hare-lip should be repaired at the earliest convenient moment. The operation is reasonably safe, and the cosmetic result is often permanently successful; moreover, repair of the lip often reduces the defect in the palate, and hence makes subsequent closure simpler and more certain.

Cleft of the palate means that the child will be hard to rear, and will almost certainly suffer from under-nourishment with all its perils. The difficulties arise from the fact that sucking the breast or bottle is impossible if there is no adequate opponent for the tongue (as occurs in the major clefts of the palate), and these difficulties can only be overcome in one of two ways—namely, by the provision of a species of denture or plate for the infant, or by spoon, bottle, or fountain-pen-filler feeding. Of the former method I have no experience; the success of the latter can, I believe, be sustained only by careful and self-sacrificing perseverance on the part of the mother or nurse. Thus the child with a cleft palate has to surmount many hurdles in the first year or two of life, and it is not surprising that many succumb through inattention or indifference.

Sooner or later the question of closure of the palate has to be faced and, unfortunately, its consideration is too often postponed until the parents have observed the defective speech. The age at which this is evident seems to vary a good deal, and the lateness or earliness of speech is one of the factors which affect the results obtainable by operation. Striking an average, however, it may be said that defects are noticeable at, or before, the third year of life. In another paper[1] I have endeavoured to show how these defects arise, and how they are continued until such time as habits, difficult to eradicate, are formed. Clearly it is imperative to operate before these habits begin, and that means at or before the age of about two years.

As I have said already, many of these cases have an uphill fight and hang on to life with but slender threads. It is therefore my practice before operating on such young children to ask the guidance of my colleagues at the Newcastle Babies' Hospital, since by the mere surgeon many unsuspected cases of gross infantile disease are easily overlooked. Apart from the skilled assistance of pædiatricians no special pre-operative precautions are taken.

The Operation

Having decided that operation should be undertaken before speech has become an established habit, the next problem is the type of operation to be done, and at this point it should be recognised that the object in operating is to produce a partition between the oral and nasal cavities and to restore the palate to such a form and condition that it is able to reach the posterior pharyngeal wall and thus close off its cavity. Without this closure normal speech is virtually impossible, and a failure in this respect is responsible for a very large proportion of the cases in which bad speech remains after the classical operations. The fault in these operations lies in non-recognition of the fact that two halves of a cleft palate never together equal one whole palate, and that, owing to changes in the architecture of the whole skull, the nasopharynx is so capacious as to make it impossible for the repaired palate to meet the pharyngeal wall and thus obliterate the cavity. To be successful, then, an operation must aim either at reducing the size of the nasopharynx, or at increasing the mobility of the soft tissue in the palate. With the object of reducing the size of the nasopharynx, I devised the operation of pharyngoplasty, and, after some considerable experience, I am prepared to urge its adoption in all cases of cleft palate.

Pharyngoplasty aims at narrowing the capacious nasopharynx and at producing a ridge on the posterior pharyngeal wall, in imitation of the ridge of Passavant which normally arises in this situation during speech; against this ridge the soft palate can make contact and so close the nasopharynx. The operation is performed by making a transverse incision through the posterior pharyngeal wall at about the level of the anterior arch of the atlas and then suturing this in a vertical direction, thus narrowing the pharynx from side to side and, at the same time, producing a prominent ridge. The operation is performed using endotracheal anæsthesia, and can be carried out with precision at an early age. Observation of the results of pharyngoplasty after some years demonstrates the continued narrowing of the pharynx and is, of course, reflected in the speech results.

It is manifestly impossible to increase the amount of soft tissue in the palate, but there are many ways in which the maximum degree of mobility of the available tissue can be attained, and one of these—namely, division of the hamular processes—is of paramount importance. Division of the hamular processes sets free the tendons of the tensor muscles of the palate, these being the main obstacle to free mobility. Its efficacy can be demonstrated either on the living or the dead body, or on theoretical grounds after comparison of the normal skull with that of the cleft palate.[2]

Repair of the palate is carried out at the same sitting as the pharyngoplasty, and since each case must be judged on its merits little need be said of the exact procedure adopted. Suffice it to say that the hamular processes are always divided, and that an attempt is always made to reconstruct the nasal mucosa as advised by Veau.[3] The various flaps and incisions recommended from the time of Langenbeck onwards are used to fit the particular case.

After-treatment should not be elaborate, and during the healing process the less done to the palate the better. Feeding for the first ten days should consist of sterilised liquids, each meal being followed by a drink of sterile water. After this time, return to normal feeding should be gradual. Local treatment to the suture line is not necessary in infants.

The Results

Results of the combined pharyngoplasty and repair of the palate have given the greatest satisfaction, and my experience has been that if a child is operated on before defective speech habits have become firmly established, and if the palatal mechanism is restored (as is done in the large majority of cases), it will grow up without any of the stigmata of cleft palate speech. Such a claim may almost be regarded as fantastic in the light of experiences with classical types of operation, but nevertheless the statement is true. Moreover, this result is attained without any special training except such as can be given by the mother.

The *speech history* after operation varies somewhat. As emphasised above, most children submitted to pharyngoplasty and repair of the palate develop speech which is in every respect normal. Others pass through a phase when they develop some of the characteristic defects of cleft palate speech, but in the course of a few months, or a year or two, they lose these defects completely, so that it is impossible to say that they have ever suffered from this abnormality.

Secondary operation.—It must be a general experience that after the classical operations the majority of patients develop cleft palate speech and retain it for the rest of their lives. Such cases can often be restored to normal habits of speech by pharyngoplasty, division of the hamular processes, and some of the various methods devised for such secondary operations as I hope to publish in a further paper devoted exclusively to surgical technique. These cases nearly always require subsequent speech training, since they have acquired habits which have grown harder to overcome the longer they have existed.

Recognition of Functional Abnormality.—The question then arises as to when one has waited long enough before submitting a supposedly successful case of repair, with bad speech, to further operation. Admittedly the decision is difficult; it is going to depend on the ear, and on certain physical tests. The reference to the ear concerns the practitioner and not the patient, because nothing has retarded the progress of cleft palate surgery more than the fact that auditory acuity is low in most human beings. Practitioners vary widely in their ability to detect even quite gross defects in speech; but there are two characteristic faults which ought always to be recognisable—namely, the use of the glottic stop to replace consonants, and the formation of the pharyngeal or nasal "s." In the physical tests auditory judgment can be replaced by observation of facts. A child with cleft palate of the major degree cannot close the nasopharynx, and consequently cannot perform many of the normal evolutions such as clearing away pharyngeal mucus; in other words, he cannot snort. He cannot inflate balloons or blow soap bubbles, except with extraordinary effort in which nasal escape predominates. Hence, if operation is to be regarded as successful, the functions of snorting, balloon-inflation, and soap-bubble blowing must be carried out with facility and without real effort. In these respects, then, one has simple tests of the efficiency of one's surgical procedures, and if, despite careful speech training, any defect persists over a reasonable period after operation—say, a year or more—then secondary operation should certainly be considered. Where it can be proved that the patient can close the nasopharynx, as shown by the physical tests, no further surgical interference is required, and training should be continued.

The necessity for *speech training* is in my opinion an admission of surgical and physiological failure, but there is no doubt that such training plays a very important part in the after-treatment of the cases of cleft palate in which surgical failure has occurred, or in which the operation has been delayed too long. Speech training as carried out by Miss Freda Parsons of Birmingham is very impressive, since undoubtedly, as Miss Parsons claims, it is associated with pharyngeal and palatal muscular development. The attainment of a good result by speech training, however, is a long and laborious process which may extend over years without the attainment of perfection. Further, many of those trained are capable of excellent speech in the presence of their teacher, but make no attempt to use their training in the ordinary affairs of life. Again, trained speech very often lacks the carelessness and slovenliness of ordinary conversational English. This is no veiled and underhand shot at those who are doing magnificent and painstaking work ; it is merely a plea that the unfortunate sufferers from cleft palate should be submitted to early and physiological operation in order that they may be allowed to develop speech in a natural fashion.

THE USE OF PURIFIED CASEIN IN SALT-FREE DIETS

By E. M. Widdowson, B.Sc., Ph.D.
ASSISTANT BIOCHEMIST, KING'S COLLEGE HOSPITAL, LONDON ; AND
R. A. McCance, M.D., Ph.D. Camb., F.R.C.P. Lond.
ASSISTANT PHYSICIAN IN CHARGE OF BIOCHEMICAL RESEARCH AT THE HOSPITAL

Synthetic Milk

Milk is generally forbidden when a patient is prescribed a strictly salt-free diet. The usual substitute is cream, which is quite satisfactory for many purposes, but it has obvious disadvantages for young children. Further, if the case to be treated is one of nephrosis with normal powers of nitrogen excretion, a reduction of the protein intake by substituting cream for milk may not be advisable.

A synthetic milk containing almost no sodium chloride has now been devised and used both therapeutically and experimentally. It is relatively easy to prepare and is a very fair substitute for natural milk. It is made from water, lactose, cream (United Dairies Ltd.), "ashless" casein (Glaxo Laboratories), and a salt mixture containing calcium, magnesium, potassium, iron, and phosphorus. Lactalbumen has not been added owing to the difficulty of obtaining a salt-free preparation of this protein (*vide infra*). The composition may, of course, be altered to suit individual requirements, and two varieties are here described. The first, which was made up as nearly as possible to a cow's milk formula, was quite palatable, and was used successfully in treating a child of 15 months with massive œdema and a normal blood-urea. This milk had, however, a slightly gritty taste, presumably owing to the rather high content of insoluble calcium salts. A second milk was therefore made which contained the amounts of protein, fat, and carbohydrate found in cow's milk, but in which the salt content was considerably reduced, so that the amounts of calcium, phosphorus, magnesium, and iron approximated very closely to the amounts of those elements found in human milk. This second milk is decidedly smoother in taste, and is recommended where a high mineral content is not required. Both milks prepared according to the directions below are neutral to litmus, and they can be kept for several days in a cool place.

PREPARATION OF MILKS

The following solutions are used :—

Stock Solution A.—Normal KOH (5·6 per cent.).

Stock Solution B. (Cow's milk formula.)—KH_2PO_4, 20·4 g., calcium lactate, 33·7 g., $MgSO_47H_2O$, 6·5 g., and $FeSO_47H_2O$, 0·10 g. (made up to 500 c.cm.).

Stock Solution C. (Milk with low mineral content.)—KH_2PO_4, 3·05 g., calcium lactate, 6·2 g., $MgSO_47H_2O$, 2·0 g., and $FeSO_47H_2O$, 0·10 g. (made up to 500 c.cm.).

B and C are not true solutions since some of the calcium salts are present in suspension.

Half a litre (18 oz.) of synthetic cow's milk may be prepared as follows :—

20 g. of ashless casein are suspended in 420 c.cm. of water, and 24 c.cm. of normal KOH (Solution A) are added. The mixture is heated to boiling with constant stirring. Then 50 c.cm. of stock solution B are added, and the milk is again boiled. It is allowed to cool and 25 g. of lactose and 2 oz. (60 g.) of cream are added.

The second variety of milk, with a lower mineral content, is prepared as follows :—

20 g. of ashless casein are boiled with 430 c.cm. of water and 13 c.cm. of normal KOH (solution A). Then 50 c.cm. of stock salt solution C are added and the mixture is again boiled. After cooling, 25 g. of lactose and 2 oz. of cream are added as before.

Precautions.—It is necessary to adhere closely to the prescribed conditions to obtain a smooth and homogeneous preparation, and the cream should not be added until the milk is nearly cold. Lactose is easily charred by hot alkali, and it is important that it should not be added until the milk has been neutralised by the stock salt solution. All preparations of casein may not have exactly the same alkali value. It may be necessary, therefore, to make small adjustments in the amount of KOH required to render the final product exactly neutral.

Since aluminium is so readily attacked by alkali, a saucepan of this material should not be used in the preparation of the milk.

Table I.—*Mineral Composition of Natural and Synthetic Milks* (mg. per 100 c.cm.)

—	Cow's milk, natural.*	Cow's milk, synthetic NaCl-free.	Human milk, natural.*	NaCl-free synthetic milk. Low mineral content.
Calcium ..	120	120	22·6	22·6
Phosphorus	94	94	14·0	14·0
Sodium ..	43	4	43	4
Chlorine .	93	6	87	6
Potassium.	156	304	74	118
Magnesium	13·5	13·0	4·1	4·1
Iron	0·11	0·4	0·096	0·4

* Analysis from McCance, Sheldon, and Widdowson.[1]

COMPOSITION AND USES

Table I. shows the relative mineral compositions of cow's milk, human milk, and the two varieties of synthetic milk. It will be observed that the two synthetic milks contain more potassium than do the corresponding natural milks, but physiologically there is no objection to this. Some of the extra potassium replaces the sodium found in the natural milk, and the remainder must be added to obtain a neutral solution if the calcium is added as the soluble lactate. The traces of sodium and chlorine are derived from the added cream.

The synthetic milks may be used for most purposes for which cow's milk is generally employed. They may be used for infant feeding, and for this purpose they may be sweetened with cane sugar. More cream may of course be added if desired. No claim is made that the milk is a "perfect" food for a growing baby. Owing to the omission of lactalbumen it may, for example, be deficient in cystine. A supplement of cystine could be added if a salt-free milk was to be the sole article of diet for a considerable time. For most purposes however this will be quite unnecessary, since casein is admittedly a protein of high biological value. Similarly, small amounts of copper could be added if desired.

Further it is to be noted that these synthetic milks contain no vitamin C. The added cream will supply some vitamins A and D but probably not enough for a growing child.

For older patients the milk may be used in tea, and in coffee and cocoa it is quite indistinguishable from ordinary milk. It has been used for cooking with considerable success, and in rice pudding, blancmange, milk jelly, and powder-custard, the slight flavour of the casein cannot be detected.

COST

"Ashless" casein, which is a "special acid-washed first grade acid casein," has been used throughout and costs 4*s.* per kg. Half a litre (18 oz.) of milk prepared as previously described costs about 6*d.* (casein 1*d.*, lactose 1*d.*, cream 4*d.*) A cheaper preparation of NaCl-free casein, "1st quality casein," costing 2*s.* 9*d.* per kg. has been investigated. Milk prepared with this casein is possibly not quite so palatable, and its price is only reduced by ½*d.* per 500 c.cm.

Salt-free Casein Bread

Salt-free diets with a high or even normal protein content are difficult to construct since the foods rich in protein—meat, fish, cheese, eggs, and milk—are those which contain a relatively high percentage of sodium chloride. A salt-free bread containing ashless casein has proved to be extremely useful in these cases, and it is almost indistinguishable from home-made salt-free bread prepared entirely from flour. This bread is made from 640 g. (22½ oz.) of flour, 156 g. (5½ oz.) of ashless casein, 15 g. (½ oz.) of yeast, and 425 c.cm. (15 oz.) of water, and is mixed and baked in the ordinary way. The relative compositions of ordinary bread and casein bread are shown in Table II. The cheaper casein would reduce the cost of 1 lb. of bread by about 1*d.*

TABLE II

	Ordinary bread (Plimmer [2]) g. per cent.	Casein bread g. per cent.
Protein	7·0	19·7
Carbohydrate	47·4	42·5

Summary

(1) A method is described for the preparation of two varieties of synthetic milk containing a negligible amount of sodium chloride. One milk has approximately the same composition as cow's milk, while the other has a lower mineral content. (2) The preparation of a salt-free bread containing 19·7 per cent. of protein is also described.

We wish to thank Miss B. Swayne for her assistance with the cooking. One of us (E. M. W.) is indebted to the Medical Research Council for a part-time grant.

A NOTE ON THE VALUE OF THE DRINKER RESPIRATOR IN DIPHTHERIA, EMPYEMA, AND PULMONARY COLLAPSE

By MAURICE MITMAN, M.D., M.R.C.P. Lond., D.P.H., D.M.R.E.

ACTING DEPUTY MEDICAL SUPERINTENDENT, NORTH-EASTERN HOSPITAL, L.C.C. INFECTIOUS HOSPITALS SERVICE: AND

NORMAN D. BEGG, M.D. Aberd., D.P.H.

SENIOR ASSISTANT MEDICAL OFFICER TO THE HOSPITAL

THE Drinker respirator [1] has been employed in America since 1929 for paralysis of respiration in poliomyelitis, alcoholic coma, drug poisoning, drowning, and asphyxia neonatorum. Gordon, Young, and Top [2] in 1933 reported two cases of post-diphtheritic respiratory paralysis treated in the respirator. They were impressed by the possibilities of use of the apparatus for this condition. Since February, 1934, the first respirator purchased by the London County Council for use in its infectious hospitals has been stationed at the North-Eastern Hospital. This paper is a preliminary note on the use to which the apparatus has been put; a more detailed report is to be published later. Eight cases of diphtheria and two of empyema thoracis were treated.

IN DIPHTHERIA

The paralytic stage of diphtheria occurs roughly from the third to the sixth weeks. The manifestations suggest lesions of the nervous system. Our view is that these are central (bulbar), not peripheral. This is of importance because Wilson,[3] in discussing the types of respiratory failure in poliomyelitis, expressed the view that those of bulbar origin were the least amenable to treatment in the respirator. Paralyses, when they occur, tend to affect structures in a more or less regular sequence: the palate, the eyes, the heart, the pharynx, and the diaphragm being a common order. The last two often occur together. Death in this stage may be due to concomitant circulatory failure, but is usually the result of respiratory failure or broncho-pneumonia. Involvement of the lungs is of considerable importance in deciding whether a case is suitable for the respirator. It depends either directly upon the paralysis of respiration or is secondary to accumulated mucus in a paralysed pharynx. The function of the Drinker respirator is to replace or augment the failing respiratory musculature.

The eight cases of diphtheria were all severe, with extensive oro-pharyngeal membrane and moderate or severe toxæmia. All except two were given intravenous as well as intramuscular antitoxin. The doses varied from 64,000 to 160,000 units. In all except two there was clinical and/or electrocardiographic evidence of severe cardiac damage. Two cases (which recovered) had complete heart-block. The time of onset of paralytic phenomena varied from 17 to 40 days, but the diaphragmatic paralyses were strikingly consistent in their time of appearance: forty-second to fiftieth day. Of the eight cases, five recovered and three died. The experience culled from the series may be summarised thus:—

1. Cases must be put in the respirator early—as soon as diaphragmatic paralysis is suspected; otherwise there is considerable danger of broncho-pneumonia developing.

2. When exudative changes are present in the lungs the respirator is of little or no value.

3. The pharyngeal paralysis which so frequently accompanies the diaphragmatic must be treated thoroughly. Owing to the fact that the respirator employed was not tiltable, the valuable procedure of postural drainage could not be employed. Mechanical aspiration and manual removal of mucus are, however, adequate if carried out thoroughly. Nasal feeding is usually necessary and should be done without stopping the machine.

4. The patient should be retained in the respirator continuously. Among the recoveries, the shortest period necessary was 4 days and the longest 15 days. This provides valuable, and hitherto unknown, information concerning the natural duration of diaphragmatic paralysis in diphtheria. When there are signs that movement of the diaphragm is returning, the patient can be tried without the apparatus for short periods.

5. If the respiratory rate of the patient is grossly abnormal, no attempt should be made to synchronise the respirator with it; rather the apparatus should be adjusted to a rhythm of about 20 per minute in the expectation that this will be imposed upon the patient.

6. Positive pressures are without advantage and sometimes produce discomfort. Negative pressures need not be great. A variation of from 0 to −16 or −18 cm. of water is usually the maximum required. Hyperventilation, which has been practised in America to produce periods of apnœa whilst the patients are receiving attention, was not attempted in our series.

7. A patient who is going to improve responds in a definite manner: (*a*) His respiratory rate adjusts itself almost immediately to that of the machine. (*b*) Cyanosis and dyspnœa rapidly disappear. (*c*) Restlessness, due largely to violent respiratory efforts and the consequent embarrassment of a heart already labouring under difficulties, disappears. The rate of the pulse falls, its quality improves, and not infrequently the patient falls into a restful slumber. This sedative effect can be most striking. Cases which fail to respond in this way are unlikely to derive benefit from the respirator. Such cases are usually those in whom broncho-pneumonia has appeared.

8. The equable and slightly raised temperature which was maintained inside the respirator by the heating lamp appeared to have a beneficial effect upon the circulatory collapse which occurs in this stage of the disease.

Of the five cases which recovered, four would certainly have died without the assistance of the respirator. Of the three deaths, two had evidence of commencing broncho-pneumonia before entering the respirator. In both the respiratory rate of the patient failed to adjust itself to that of the machine; in consequence no relief was provided. One was in for four hours only, the other for five hours. In the third case the respiratory distress was relieved, but death appeared to be due to circulatory failure of bulbar origin.

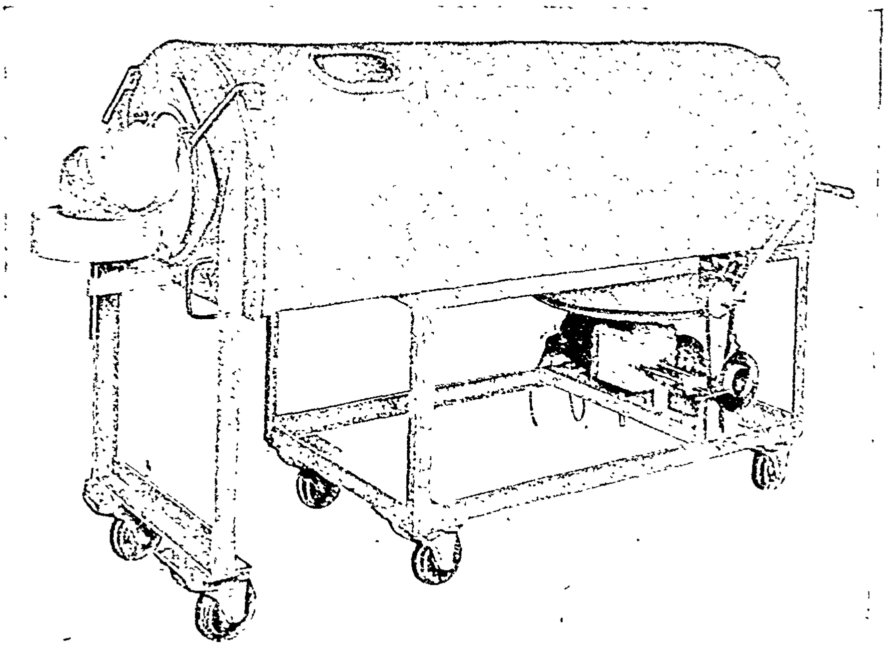
IN EMPYEMA

We have been unable to find any reference in the literature to the use of the Drinker respirator in empyema. The two cases here described suggest a new and valuable field for the use of the apparatus.

The first case was that of a child of 1¾ years, admitted for measles and broncho-pneumonia. A localised empyema in the right middle and outer pulmonary zone was treated by aspiration and later by rib resection. Progress was extremely slow, and 54 days after the operation the wound was still discharging. As the child was too young to be taught to inflate its lungs by respiration against resistance, it occurred to one of us (M. M.) that the respirator might be usefully employed to expand the lung by negative external pressure. The healthy side of the chest was strapped and the patient put in the respirator for one hour daily at pressures of 0 to −18 cm. of water. Four such treatments sufficed to expand the lung and the wound healed six days later. A later X ray showed only a narrow band of opacity to indicate the site of the former cavity.

The success which attended this experiment was so immediate and so striking that it was decided to try another case which was proving troublesome. This was not a simple case such as the one just described. Nothing definite was hoped for and, as it happened, a successful issue was not obtained, but definite improvement occurred.

This case, a female of 4 years, had previously suffered from asthma and several attacks of pneumonia. She was admitted for whooping-cough and pneumonia. Six weeks after admission she developed an interlobar



To illustrate the type of respirator used. The enamelled steel chamber encloses the whole of the patient except the head; a sorbo-rubber collar forms an air-tight junction at the neck. The variations in pressure are produced by the electrically-driven bellows, which can be seen at the foot of the apparatus above the motor.

(From a block lent by the manufacturers, Messrs. Siebe, Gorman and Co., Ltd., London.)

empyema which ruptured into a bronchus and infected the general pleural cavity. Despite a rib resection, progress was negligible; the wound continued to discharge and several X rays revealed an empty cavity in the mid-pulmonary field with collapse of the lung base. As all efforts at inflation failed to expand the lung, she was treated in the respirator on the same lines as Case 1. The discharge diminished at once and her general condition improved. An X ray showed that the basal collapse had disappeared and treatment was discontinued. The discharge immediately increased in amount, but diminished when treatment in the respirator was restarted. After seven days' treatment the discharge only amounted to an occasional head of pus, and an X ray showed evidence of permanent fibrotic changes in the lung. At the request of her parents she was discharged and allowed to attend an out-patient department.

We are of the opinion that this case derived definite benefit from the respirator. The beneficial effect was due to the fairly rapid disappearance of the pulmonary collapse. All the other abnormalities were unaffected by the apparatus.

We desire to acknowledge our indebtedness to Dr. W. Gunn, for placing his American experience of the apparatus at our disposal; and to Dr. E. H. R. Harries, medical superintendent of the hospital, for his valuable coöperation and encouragement, and for his permission to publish these cases.

ADOLESCENT COXA VARA*

BY V. H. ELLIS, B.Chir. Camb., F.R.C.S. Eng.

ORTHOPÆDIC SURGEON TO ST. MARY'S HOSPITAL, LONDON; ASSISTANT SURGEON, ROYAL NATIONAL ORTHOPÆDIC HOSPITAL

THE slipping of the upper epiphysis of the femur is a well-recognised condition occurring in adolescents. The term coxa vara was introduced in 1894 by Hofmeister[1] and Kocher, but Sprengel,[2] in 1898, made the original observation that slight trauma was sufficient in certain individuals to produce this separation. In 1913 Elmslie[3] reviewed the subject of coxa vara, with special reference to the type seen in young adolescents.

The separation occurs only between the ages of ten and nineteen, the upper limit being determined by the union of the epiphyses with the diaphyses. The reason why it is not seen much before ten may be that the cartilages of the great trochanter and the head are continuous before this age, as observed by Irwin.[4] In 1915 Walmsley[5] pointed out that at ten the epiphyseal line comes to lie more vertically, with the result that the shearing force along the line of the growth cartilage is increased

The causation is not certain, but undoubtedly several factors are at work. Trauma is certainly one, but it is often slight, and often indirect (e.g., a twist of the leg); quite frequently no history of trauma can be recorded. Kocher considered a localised osteomalacia to be the cause, and Wardle[6] has described areas of apparent rarefaction in the metaphyses.

A large proportion of the patients show Fröhlich's syndrome, but it is possible that the increased weight is purely traumatic in its effect.

The seven cases considered in this paper are a personal series, and for that reason the numbers are unfortunately small. Two points may, however, be noted:—

(1) Whereas the boys are often of normal physique (with a history of trauma), the girls are apt to be obese (4 out of 5 *in this series*). They may weigh as much as 2 st. above the average for their age.

(2) A definite history of trauma was obtained in only 2 cases out of 7. In one of these there were premonitory symptoms—a common feature of the condition.

SYMPTOMS AND DIAGNOSIS

Adolescent coxa vara forms about 1 per cent. of orthopædic cases. It is notorious, however, that these cases are rarely diagnosed before admission to hospital, although in the early stages, before deformity has occurred, there should be no difficulty in their recognition.

Pain is usually the first symptom and may precede any others by weeks; it does not, as a rule, follow trauma. The pain is gradual in onset, is often described as rheumatic, and may be referred to the hip or knee. After a short time it becomes sufficiently severe to warrant medical attention and X ray examination. In the preliminary stage of this condition—as so often also in tuberculosis of the hip—radiography may be negative. There may, however, be slight areas of rarefaction visible on the diaphyseal side of the epiphyseal cartilage, and sometimes the profile of the upper border of the neck and head of the femur is convex upwards—that is, slipping has commenced.

As soon as pain is at all severe a limp will be noticed. Any child between the ages of 10 and 19 who complains of these symptoms should be radiographed and kept in bed for a week. All transient conditions, such as mild rheumatism, should clear up by this time, whereas more serious lesions, such as coxa vara, will show a return of symptoms if the child is allowed to bear weight again after this short interval. This condition should be suspected if the child is growing very fast or shows evidence of an endocrine disorder, such as marked adiposity or Fröhlich's syndrome.

Six weeks' rest, with slight extension, is the correct treatment at this stage. The condition is sometimes bilateral though usually not simultaneous. It does not affect the general health. After some weeks, and often as the result of moderate trauma, displacement occurs. If the onset is sudden there is extreme pain and inability to walk. In any case, an obvious limp will be noticed, partly due to shortening and partly to limitation of hip movement. Eversion of the foot is always present, and may be very conspicuous. The hip appears flattened, and some fullness over the front of the joint may be detected. Movements are limited except extension and adduction; abduction is very limited and internal rotation not allowed.

TREATMENT

Treatment of adolescent coxa vara by simple traction has been adopted by many surgeons, yet its efficacy and results do not seem to be widely known.

Until quite recently the orthodox treatment consisted in forcible reduction of the deformity by wide abduction of the affected hip under anæsthesia, and prolonged fixation in the corrected position by means of a double plaster spica. Most people will agree that the results were not very satisfactory; stiff joints and the subsequent development of severe arthritic changes were common, while the original deformity often remained unreduced. Subtrochanteric osteotomy of the deformed femur often gave good functional results, and this is still the method of choice where the deformity cannot be reduced. I propose to eal here with those cases in which deformity has not et occurred, or is reducible by simple skeletal raction.

---

* Based on a paper read to the British Orthopædic Association on Nov. 3rd, 1934.

The X ray photograph of a typical case of adolescent oxa vara (Figs. 1–3) shows that the head has remained n its normal position in the acetabulum, while the eck of the femur (1) has risen an inch or so; 2) is adducted; and (3) is externally rotated as shown y the lesser trochanter being in profile.

The raw surface of the neck looks very much upwards nd forwards, and only to a slight extent inwards. aturally, Shenton's line is lost.

As the position of the head cannot be controlled eduction must be effected by changing the position f the neck. This was the principle of forcible reduction y abduction and internal rotation, but in that ethod the fulcrum about which the femur rotated was the point at which the lower edge of the neck impinged upon the head, thereby causing severe trauma to the atter, and possibly tearing of the lower part of the apsule as well. It is this fact which produced the bad results of this form of treatment. In 1929 Irwin[4] says:—

> "With two exceptions, out of a dozen cases which I have examined personally, the patients have suffered from pain, stiffness almost to the extent of complete ankylosis in some, and gross disability has always been present. One of the mobile cases was shown to me by H. P. Malcolm. It was unilateral, and was treated by extension for six months almost as one would treat a case of tuberculosis of the hip. A year later movements were still excellent."

Results of forcible abduction may have caused a swing of the pendulum in the opposite direction, and several surgeons who have adopted the recent method of skeletal traction have stated that the limb should not be abducted. If extension without abduction is applied, either the shortening only will be overcome, or the head will be forced back into relation with the neck by being caught between the lower lip of the acetabulum and the lower border of the neck. This would account for the slightly incomplete reduction shown in some of these cases, the end-result showing the upper border of the neck and head to be convex upwards. This appears to be the condition in the photographs of some of Wardle's[6] cases, and it is suspicious that he gives the standard of good result as "not more than ½ inch of real shortening." In the majority of his radiograms, however, it will be seen that during traction the femur is abducted. Perkins,[7] in his description of treatment, leaves the sound leg free so that traction on the affected side only causes abduction by the tilting of the pelvis.

In order to get apposition of the two fragments their raw surfaces must be brought into parallel planes, and this can only be done by abduction at the hip-joint; this is most accurately achieved by abducting the femur, during extension, to the requisite angle. When this manœuvre is employed, the fulcrum is not at the contiguous raw surfaces but at the attachment of the pubo-femoral ligament—as has been explained by R. Whitman in describing his method of reducing high cervical fractures of the femur. In addition, the tension of this ligament causes the femur to rotate internally, thus removing the third displacement—a fact which has often been observed without exciting adequate comment.

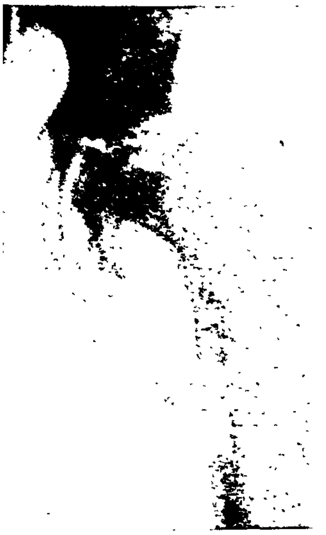

FIG. 1.—Typical adolescent coxa vara of the left hip in girl aged 11, showing complete separation of the epiphysis. Note the external rotation of the shaft of the femur.

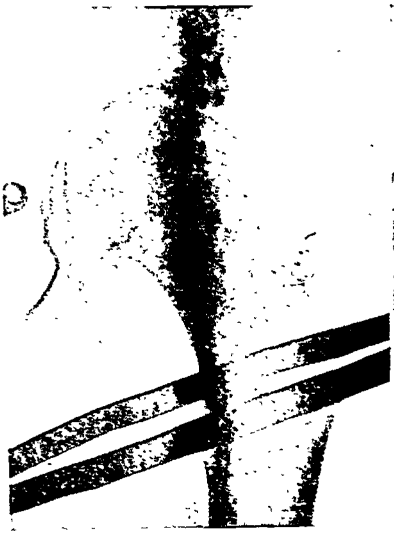

FIG. 2.—Radiogram of the same hip six months after reduction, showing complete reduction. Note upper line of neck and head, and the normal rotation of the shaft of the femur.

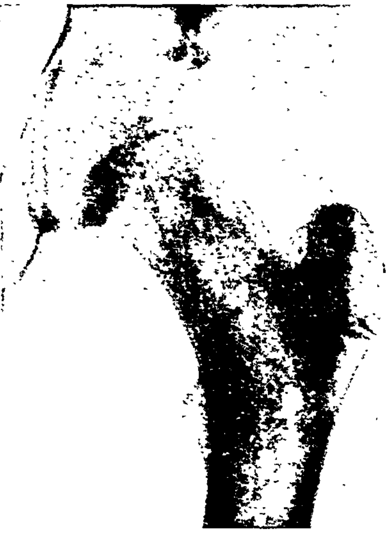

FIG. 3.—Normal hip of the same patient, the radiogram being reversed for comparison.

A SERIES OF CASES

The course of adolescent coxa vara may, as we have seen, be divided into three stages:—

1. Premonitory or pre-slipping.
2. Deformity present but reducible.
3. Deformity present and irreducible.

In the present series of 7 patients with 9 affected hips (2 were bilateral), 2 were boys and 5 girls; the age ranged between ten and sixteen years; none were examined in the first stage, though 3 called for medical advice then. Seven were in the second stage: 6 were treated by traction and reduction was effected; 1 was treated elsewhere by forcible abduction and plaster with a poor result. Two were in the third stage.

In all cases where the history of pain was six weeks or less, reduction was effected (see Table). The duration of the third-stage cases was 3 months and 9 months. Irwin[4] says that stabilisation appears to occur from six weeks to three months after displacement.

Table showing Results in the Treatment of Adolescent Coxa Vara

No.	Hip.	Age.	Sex obesity.	Length of history.	Weight extension 7 weeks.	Result.
1	L.	10	F. + +	6 weeks.	10 lb.	Complete reduction.
2	L.	16	M. –	9 months.	25 lb.	No reduction.
3	R.	13	F. +	?	?	Complete reduction.
	L.	,,	,,	6 weeks.	20 lb.	
4	L.	12	F. +	Acute onset.	None.	Very poor reduction.
	R.	13	,,	1 week.	15 lb.	Complete reduction.
5	L.	11	F. +	3 weeks acute.	15 lb.	,,
6	R.	14	M. —	?	20 lb.	,,
7	L.	11	F. +	3 months.	None.	No reduction.

The skeletal traction was obtained in the earlier cases with a Steinmann's pin, and later with Kirschner wire through the lower end of the femur, the limbs being supported in Thomas splints, each in about 30° abduction. Traction on the affected side varied from 10 to 20 lb., with counter-extension by raising the foot of the bed. The deformity having been corrected, the weight was gradually reduced after four weeks but traction was continued for seven weeks, the process being controlled by radiography. After the limb had lain loose to allow active movement, a weight-bearing calliper was worn for six months and gradually left off; during this period reduction of obesity was attempted where necessary.

Clinical investigations were carried out in some cases, but in these no abnormality was found in the blood, urea, calcium, or phosphorus estimations. The plasma phosphates figure appears to have been low, but this may have been erroneous.

In all cases where complete reduction was obtained, full range of movement was eventually present, with the exception of internal rotation which was slightly limited in two cases. Restoration of full range of movement to the knee was often more difficult than to the hip.

In one case an X ray photograph taken two years after complete reduction shows a slight relapse, which had apparently occurred without symptoms. Radiograms taken six months after reduction had been normal.

CLINICAL AND LABORATORY NOTES

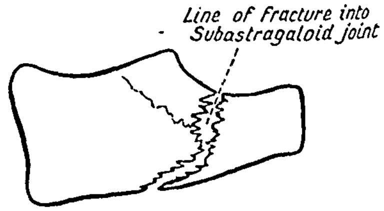
FRACTURES OF THE CALCANEUS

By D. C. Corry, M.D. Lond., F.R.C.S. Eng.
ASSISTANT SURGEON TO THE RADCLIFFE INFIRMARY, OXFORD

Since 1931, in fractures of the calcaneus involving the subastragaloid joint, I have concentrated on early movement of this joint; for only by keeping it free from adhesions can a painless foot be achieved. Normally, in walking, the shoe adapts itself to inequalities of the ground by movements at the subastragaloid and midtarsal joints. If the subastragaloid joint is limited by adhesions any slight inequality of the ground produces pain.

The fracture is caused by a fall from a height on to the heels. The body-weight, transmitted by the astragalus, fractures the calcaneus. The deformity which develops in a very severe fracture has been described by Böhler: the posterior fragment is pulled upwards by the tendo Achillis, flattening the posterior pillar of the longitudinal arch of the foot; the posterior fragment is also drawn forward by the short muscles of the sole of the foot, and the os calcis becomes broadened. Such displacements, if present, must be corrected by the special methods of Böhler, but as a rule they do not occur.

The treatment I adopt is as follows. The foot is encased in plaster applied over stockinette, the plaster being continued up the leg to just below the knee. A Sorbo rubber heel is fitted to the plaster and the patient is encouraged to walk about and to exercise his toes. At the end of three weeks the plaster is split down each side and the foot is taken out three times a week for movements of the subastragaloid joint. With the patient lying on a couch the astragalus is gripped by one hand of the masseur. The patient is encouraged to relax the muscles of his leg, and the masseur with his other hand inverts and everts the calcaneus. Movement at the subastragaloid is difficult to distinguish at first; for when it is absent the soft tissues over the calcaneus move and give a feeling of movement at the subastragaloid joint, which may deceive the inexperienced masseur. When the movement is really present, however, there is no doubt about it. During the period of split plaster no weight is taken on the plaster, and the patient moves with crutches. At the end of 8 to 12 weeks, depending on the size of the crack, normal weight-bearing is permitted.



The following notes summarise four cases treated by this method:—

Case 1.—On Oct. 31st, 1931, the patient fell 20 feet on to his heels, sustaining a bilateral fracture of the calcaneus. End result: moderate movement of the subastragaloid joint. Can walk only four miles, after which foot gets painful.

Case 2.—On August 10th, 1932, patient fell 10 feet off a ladder and fractured his calcaneus. Treatment was given and patient was walking eight weeks later. Two weeks later the subastragaloid movements were still poor and walking painful, and the foot was manipulated under an anæsthetic. Böhler's "redresseur" was used as a wrench to grip and move the calcaneus. A report on Nov. 29th, 1934, states that the foot is practically normal; patient can walk any distance, and gets slight pain only occasionally in changeable weather. Not affected by uneven ground.

Case 3.—On Nov. 19th, 1932, patient fell on to heels. Discharged twelve weeks later. Is now able to walk six miles without pain.

Case 4.—Fell 5 feet off ladder on Oct. 10th, 1934. Ten weeks later no subastragaloid movements present and walking extremely painful. Masseur changed. Two weeks later subastragaloid movements obtained. Three weeks later able to walk two miles free from pain.

Fractures of the calcaneus are comparatively rare, forming only 0·25 per cent. of the fractures I see in my clinic. Malpas[1] in 1927 reported that the end-result of 25 cases he had examined depended on the degree of movement of the subastragaloid joint: those with limited movement from fibrous adhesions were painful. In my small series I have aimed at preserving a full range of movement in this joint, and the result has been that all the patients have returned to the work in which they were previously engaged.

A CASE OF "BOTRYOMYCOSIS"

By Frank Marsh, M.D. Lond., D.T.M. & H.

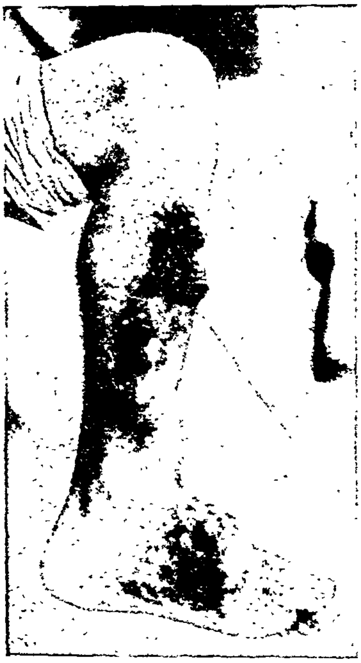
PATHOLOGIST TO THE ANGLO-PERSIAN OIL CO., LTD.

On March 25th, 1934, a male Persian, aged 18, of the coolie class, was admitted to the Isolation Hospital, Masjid-i-Suleiman, for observation. As the accompanying photograph shows, he had an extensive verrucose sessile nævoid tumour on the inner and anterior aspect of the left shin, and on the dorsum of the left foot. The tumour was not hairy and was darker than the unaffected skin of the leg; the hard verrucose granulations were situated on the summit of comparatively soft dome-like swellings which easily subsided on pressure with the fingers, but resumed their shape immediately the testing finger was withdrawn. The patient stated that the tumour had existed for "many years."

On admission the boy was thin and obviously undernourished, but otherwise normal. He had no pain but the tumour seemed tender, although he allowed the observer to incise the swelling on the foot and to remove sufficient for histological examination without much fuss. The incision bled profusely, and it was then discovered that the patient's apprehension had been on account of feared loss of blood, he having had experience of troublesome bleeding after slight injuries to his tumour.

Investigation.—(1) On applying Gram's stain the blood obtained from the tumour showed many pus cells, with intracellular and extracellular Gram-positive cocci in great profusion; there were also some diphtheroids. No acid-fast bacilli could be found. (2) Culture on glucose broth showed many streptococci of *viridans* type. On blood-agar many staphylococci and diphtheroids were grown; the latter, injected into a guinea-pig, were not virulent. A mixed staphylococcal and streptococcal vaccine was prepared. (3) A blood Wassermann test gave a positive reaction (nomenclature of League of Nations Health Committee). (4) The report on a section was as follows: "The basis structure seems to be a cavernous hæmangioma, with a very loose fibrous tissue framework. There is slight chronic inflammation in the deeper parts of the section; in the superficial layers there is well-marked chronic and acute inflammation, amounting to sepsis, and with hæmorrhagic effusions into tissue spaces. The inflammatory reaction is not characterised by any cellular or structural changes that throw any light on the ætiology of the condition." The typical botryomycotic bodies were not seen in sections stained with hæmatoxylin and eosin, by Weigert-Gram, or with toluidin blue.

Treatment.—The patient was watched until May 16th, 1934; his pulse and temperature were normal throughout, except on two occasions when he received injections of 0·45 g. N.A.B. (neoarsphenamine), each of which produced rather a severe reaction with a temperature of 101° F. Graduated doses of his vaccine produced no reaction. The lesions were painted daily with tincture of iodine. Mist. hydrarg. et pot. iod. three times a day for six weeks was administered. During the two months the patient was under observation his general health improved markedly, and he put on a stone in weight, but the tumour showed little or no alteration. It was then decided to give him an anæsthetic and scrape the growth away. On learning of this decision the patient discharged himself and has not been seen again. The N.A.B. was not pushed because the reaction after the second dose was worse than after the first. It is fairly clear that surgical removal of the tumour is the only treatment that would have been effective. The patient however seemed unwilling to lose the growth once his general health had improved; later it was discovered that the impressive appearance of the growth was a definite financial asset to him in his *profession* of beggar.



The growths on the leg and foot.

Castellani and Chalmers[1] consider botryomycosis to be a definite clinical entity. They say: "Sections show many young blood-vessels and vascular spaces which are surrounded by young connective tissue containing polymorphonuclear cells in which diplococci can easily be seen. In the very early stages the botryomycotic bodies cannot be seen. Later the growths are formed of dense fibrous tissue. The vascularity of some lesions is very marked, and Heuck considers that the condition is divisible into two categories, viz., the angiomatous and the simple. In the tropics the angiomatous is the common type." (They have, as illustration in their article, a good photomicrograph of a section which is almost identical with portions of the section examined here.)

MacLeod[2] states that "the name botryomycosis was originally applied by veterinary surgeons . . . from the belief that the lesion was due to an organism known at the time as a botryomyces . . . this view is no longer held and such lesions are now regarded as being of pyogenic origin."

In my opinion this case, which, clinically, was a typical botryomycosis at the time of observation, originated as a congenital verrucose nævus of the linear type, inclining to the ichthyosis hystrix variety, which later became infected superficially with staphylococci and streptococci, the outer layers of the lesion being thus converted into a granuloma pyogenicum.

I am indebted to Dr. E. Jamieson, chief medical officer, Anglo-Persian Oil Co., Ltd., for permission to publish this paper.

MEDICAL SOCIETIES

SOCIETY OF MEDICAL OFFICERS OF HEALTH

AT a meeting of the fever hospital medical services group of this society on May 31st, with Dr. H. S. BANKS, the president, in the chair, a discussion on the

Incidence and Management of Scarlet Fever Otitis

was opened by Dr. MURDOCH MCGREGOR. He began by referring to the statement of E. L. Ross (1924) that 10 per cent. of deaf-mutes and 10 per cent. of all cases of chronic otitis media owe their condition to scarlet fever. This made it exceedingly important that adequate measures should be taken in fever hospitals for the prevention and treatment of the acute stage. The incidence of otitis media complicating scarlet fever had not, in general, declined materially since the war, despite the mildness of the disease and despite serum treatment—in so far as the serum was given intramuscularly. In considering the incidence in any series it was important to know the proportion of cases under five years of age, since by far the heaviest incidence fell on this age-group. At the Park Hospital, London, the incidence in a large number of cases of about normal age composition (25 per cent. under five years) and treated with serum intravenously was 1·9 per cent.—a really encouraging figure.

Otitis media did not always proceed to suppuration. Routine inspection of ear drums revealed a small proportion of low-grade inflammations which usually subsided slowly over several weeks. This condition must be supervised if the child was discharged from hospital before it subsided completely. At the Park Hospital the ear drums of all cases about to be discharged were now inspected. Bacteriological examination of the discharge taken direct from the tympanum with suitable precautions showed pure cultures of hæmolytic streptococci during the first week or two: thereafter secondary infection with skin organisms tended to occur, and the latter gradually replaced the hæmolytic streptococci in the more chronic cases. A rigidly aseptic meatal toilet was therefore advocated—e.g., sterile wool mops, frequent deep meatal mopping followed by hygroscopic (glycerin and spirit) drops, and lastly the application of ointment to protect the skin of meatus and pinna. Routine early paracentesis before the membrane ruptured was an impracticable ideal. Often the first sign of otitis media in children was a discharge from the ear. Routine examination of all ear drums at least once daily had been attempted for a short time—e.g., at Los Angeles—but the labour and expense involved were beyond reason, although results were good.

For the cure of the discharging ear and prevention of chronicity Gardner (1922) and Harries and Gilhespy (1924) advocated early removal of adenoids, but Layton (1925) from experience in London fever hospitals was unable to support this thesis. Dr. McGregor proceeded to describe results of treatment of a consecutive series of 152 cases of aural discharge following scarlet fever, under the general supervision of Mr. T. B. Layton at the Park Hospital. No operative treatment of tonsils and adenoids was performed. An otological record of every case was made during treatment and just before leaving hospital. Treatment consisted of the meatal toilet described above, combined in some cases with zinc ionisation. Prognosis was found to be influenced by three factors: age (the younger the child the worse the prognosis); the presence of intercurrent infectious disease; and the treatment of the acute stage of scarlet fever with intravenous serum. The results of treatment showed a marked improvement on Layton's (1925) published results, especially in the age-groups beyond five years. The powerful new factor in the improvement appeared to be the intravenous serum treatment of the fever itself. Almost perfect results were obtained where zinc ionisation was used in the serum-treated cases, and controls treated without serum were not so satisfactory. The explanation of this difference seemed to lie in the good general condition and rapid subsidence of the nasopharyngeal congestion in the serum-treated cases. Experience with otitis following measles, in which zinc ionisation had little effect, apparently confirmed this view.

The PRESIDENT reviewed the statistical basis of the work at the Park Hospital described by Dr. McGregor. The incidence of scarlatinal otitis media as late as 1933 in the whole of the L.C.C. acute fever hospitals (19,069 cases) was 8·0 per cent. In published series of cases treated with intramuscular serum it varied from 3·5 per cent. (Harries 1930) to 8·4 per cent. (Craig, 1928). On the other hand, the incidence in his Leicester cases treated with intravenous serum was 0·9 per cent., and in his London series (1933 and 1934) 1·9 per cent. The latter results were very similar when corrected for age-distribution, and they demonstrated the remarkable effect of intravenous serum in reducing the incidence of otitis media. As regards prognosis, the age-group 0–2 years was the worst, 51·4 per cent. failing to clear up in an average period of eight weeks, but none of these children had had intravenous serum. After 2 years of age there was a steep fall in the number of cases failing to clear up within eight weeks; the figure was 14 per cent. in the age-group 2–5 years, and only 2·8 per cent. in the age-group 5–15. The presence of intercurrent upper respiratory infections—e.g., nasal diphtheria, measles, whooping-cough, or tonsillitis—had a very bad effect on prognosis, 29 per cent. failing to clear up, as compared with 15 per cent. for simple scarlet fever. Further, the duration of the otorrhœa (in the successful cases) was almost doubled. The most striking factor in the prognosis was intravenous serum treatment, only 13 per cent. failing to clear up as compared with 28·2 per cent. in controls receiving no serum. With zinc ionisation in simple scarlet fever, 32 dry ears and 4 failures were obtained, as compared with 29 dry ears and 9 failures, where it was not employed. The worst combination was found in the cases treated without serum which contracted intercurrent respiratory infections. In this group even with zinc ionisation there were as many as 10 failures in 23 cases.

Mr. T. B. LAYTON said he wished to carry the discussion on to those cases which remained uncured at the end of the eight weeks. The first problem was to get these resistant ears dry, and thus prevent otological tragedies—such as sudden death from meningitis—in later life. The local treatment depended upon a principle, quoted by Lister in THE LANCET in 1867, that an inflammation tends to get well by itself if you remove the cause of the irritation. At this stage the products of the inflammation were responsible for keeping it going, and the removal of pus from the external auditory meatus was necessary to allow fresh pus to flow out from the middle ear. In other words improved education of the nursing profession was the most important factor in the treatment of ear disease. In addition movements of the pharyngeal wall had a marked effect upon the middle ear, probably by opening the Eustachian tube and allowing drainage down it. The child should therefore be encouraged to use its pharyngeal muscles by every possible means—in laughing, singing, and by means of physical drill and nose-blowing exercises. From the point of view of getting an ear well he would rather have a child crying than stolid. It was impossible to cure otitis media in the children with the immobile faces to be seen in the glass rooms of the isolation wards; they must be taken out of such rooms if the ear was to be cured. The other way in which the cause of irritation could be removed from the middle ear was by opening the mastoid and preventing the discharge there formed from flowing over the mucous membrane of the middle ear. He called this the "clearing-up" mastoid operation, and if there were a choice between removing tonsils and adenoids or doing such an operation he would certainly prefer opening of the mastoid. It took longer to perform, and required more preparation and after-care, but from the patient's point of view it was a far smaller operation. People generally seemed not to realise how severe an operation to a child might be that of removal of tonsils and adenoids, with its three large wounds open on the surface and considerable trauma to the underlying tissues.

The second problem concerned the cases which were clinically well but which had some residual deafness or hardness of hearing. This was an educational problem, and he thought that a duty rested upon the medical profession to inform the educationists at once as soon as there was some suspicion of its having arisen. Presumptive evidence of deafness came under three heads: (*a*) where the illness had been a very severe one; (*b*) where on otological examination considerable destruction of the drumhead was seen; and (*c*) where there had been some suspicion of deafness during the stay in hospital. In all cases where there was such presumptive evidence there should be a special examination shortly after leaving the fever hospital. In Mr. Layton's opinion there should be set up in every area a liaison between the medical authorities in charge of the infectious hospitals and the educational authorities whereby every such case arising under the former was reported to the latter.

Dr. E. H. R. **Harries** said that, in his opinion, otitis media was the complication least likely to be affected by injection of antitoxin. Reference had been made to the Birmingham 1921–22 series (published by himself and Gillespy in 1924) in which none of the cases were treated with scarlet fever antitoxin (not then available) and in which the incidence of otitis media had been considerably higher than in a series treated with intramuscular serum in 1930. In 1921–22, however, scarlet fever although already a mild disease was less mild than in 1930. In 1934 the disease was of trifling clinical severity, septic types of case being few and far between. Further, in 1921–22, early post-war years, nutrition was not satisfactory, and also the patients were mostly nursed in old, large and overcrowded wards. The bed-spacing of the 1930 series was much more favourable, whilst in a later (1934) London series, all treated with antitoxin intramuscularly, 12 ft. of wall space between bed-centres had been rigidly maintained. Dr. Harries stressed the vital importance of adequate bed-spacing not only in the elimination of droplet re-infection of the upper respiratory tract but in the prevention of hurried nursing by an overworked staff which resulted in manual transference of infection from the upper respiratory tract of one child to that of another. He thought that while the opinion originally expressed by the Dicks that scarlet fever antitoxin, by abolishing toxæmia, the better enabled the patient to withstand bacterial infection was probably true, he had at present no *proof* of its effect upon scarlet fever otitis.

Dr. A. T. W. **Powell** referred to the follow-up which had been in operation in Walthamstow for some years. Cases discharged from the isolation hospital were seen at a weekly out-patient clinic in order to control late complications and to assess fitness as to school attendance. Those cases of chronic otorrhœa which had not responded to treatment in hospital were referred to the next following weekly aural clinic in the clinical care of Dr. A. R. Friel, who was also consultant aurist to the isolation hospital. Such cases rarely failed to respond to ionisation treatment; but arrangements existed for the reference of cases of chronic otorrhœa and mastoiditis for operative treatment at two local general hospitals.

Dr. **Dunstan Brewer** (Swindon) said that in the provinces some of the troubles to which Mr. Layton had referred did not exist, for the health services were not discoördinated as they were in London. For some years he had aimed at not discharging from the isolation hospital any child still suffering from ear disease. For 16 years he had been able to succeed, though recently there had been some failures. He supported strongly the conservative treatment of scarlet fever otitis.

Dr. E. W. **Goodall** drew attention to the necessity for caution in drawing conclusions from sets of figures in which many variables appeared. Dr. Harries had spoken of the decline in the severity of scarlet fever during recent years. Otitis occurred most frequently in the severe cases, so that along with this decline there had also been a reduction in the incidence of otitis—as had been shown in a report published by the Medical Research Council six years ago in respect of the Eastern Hospital, Homerton. Of the principal complications of scarlet fever otitis had been the only one to show a decline. There was also a suggestion that severe cases and therefore otitis were commoner in epidemic times. All these facts had a bearing when one was considering the results of treatment.

ROYAL SOCIETY OF MEDICINE

SECTION OF PSYCHIATRY

A MEETING of this section on June 18th considered the relation to psychiatry of

Vocational Guidance

The subject was introduced by Dr. C. S. **Myers**, F.R.S., who gave an illustrated demonstration of the methods now being worked out by the National Institute of Industrial Psychology, of which he is principal. Vocational guidance, said Dr. Myers, like medicine, is an art employing scientific procedure and knowledge, but dependent also on the exercise of judgment, tact, and intuition. The vocational adviser has not only to assess, by psychological and medical methods mainly of measurement, the mental and physical abilities and disabilities of the applicant in their relation to possible occupations. He has also to determine, by less scientific methods, the applicant's temperamental and character qualities, his interests, &c.—for which no tests are at present available. Further, he must consider the applicant's social, economic, and family environment, his personal and family history, and the opportunities and prospects which an occupation, otherwise judged suitable, may at the moment offer. He must have knowledge not only of the conditions of entry, course and cost of training, nature of the work, pay, prospects and available vacancies in different occupations; but also of the mental and physical abilities and the qualities of temperament and character requisite for success in each occupation.

Dr. ANGUS MACRAE said that vocational guidance, considered in relation to mental health, is primarily a prophylactic service. Its aim is to prevent the strain which results from occupational maladjustment and which may be at least a partial cause of mental breakdown. Unlike psychiatry, it is a service for the normal individual. Nevertheless, it is important that the vocational adviser should be instructed in psychopathology and that he should have the coöperation of a practising psychiatrist.

There are, he said, many more or less normal adolescents whose vocational aims are influenced by unconscious strivings such as a person untrained in psychiatry might not understand. When, in such a case, the vocational aim is an unsuitable one, the adviser, if he understands the motivation of the choice, may be able to suggest an alternative career which, in addition to being appropriate in other ways, will provide the kind of satisfaction that the individual is seeking. Further, the vocational adviser, although he does not cater primarily for abnormal persons, sees a considerable number of maladjusted young people who might be wrongly advised if their characteristics, as shown at the vocational interview, were accepted at their face value. It is therefore important that the adviser, even if incompetent to diagnose the abnormality, should be able to observe that an abnormality exists, in order that the individual may receive psychiatric attention before a final vocational decision is attempted. Again, there are difficult cases of young people who, having been unhappy in their work, seek advice when contemplating a change of employment. In such cases the vocational maladjustment may be merely a symptom of an underlying emotional maladjustment, and there is a danger that the sympathetic adviser may encourage the individual to take to the path of the rolling-stone by recommending a change of work when what is required is psychiatric treatment.

It has been suggested, said Dr. Macrae, that the psychiatrist should be solely responsible for vocational guidance. It may be questioned, however, whether this plan is either practicable or desirable. Certain psycho-analytic writings suggest that, if conducted by psychiatrists of this school, vocational guidance would be based on a one-sided view of the individual and would yield distinctly unhappy results. But it is certainly true that the psychiatrist's contribution is one of great importance. How this contribution can best be made is a problem for the future. Possibly the solution is to be found in the extension of the child guidance movement. At present there is a growing tendency for vocational advice to be given by teacher-psychologists in the school; and there is also a growing tendency for psychiatric problems in the young to be investigated at child guidance clinics. There can be no doubt that, if the school adviser were more thoroughly trained in psychology, both normal and abnormal, and if there were closer coöperation between the school adviser and the clinic psychiatrist, the vocational advice given to the child would be greatly improved.

SECTIONS OF OTOLOGY AND LARYNGOLOGY

THE summer meeting of these sections was held at the University and the Royal Infirmary, Bristol, on June 14th and 15th. The chair was occupied by Mr. E. A. PETERS (otology) and Mr. W. M. MOLLISON (laryngology).

Mr. J. MORRIS, research engineer to an electrical company in Nottingham, read a paper entitled

Characteristics and Properties of Electrical Deaf Aids

He declared that telephone manufacturers were fully alive to the problem presented by the deaf and partially deaf person, and one company, the Erichsson, had devised a special amplifier with a volume control. An instrument with this object was at present under the consideration of the British post office authorities. None of the aids now in use were required to satisfy any particular standard, and they had not been standardised. There were three kinds of electrical aids: (1) individual aids, to be worn on the person; (2) semi-portable aids, needing to be conveyed in a case; and (3) group aids for use in such places as churches. He described the construction of each kind with the aid of photographs. The first kind of microphone, which had been finished with great care, had a useful "life" of no more than 14 days, for at the end of that time the crackling was unendurable. When a receiver was employed to reproduce speech over a vibration range of 125 to 3000 double waves per second, it should be the aim to arrange that it should not give a highly efficient response at any single frequency; there should be a maximum efficiency over a wide range of frequency. Considerable advances had recently been made in regard to microphone amplifiers, especially in instruments designed to aid bone conduction. The semi-portable aid was becoming increasingly popular. The third kind represented the ideal form for help in churches and other assemblies, their chief drawback being their high cost. It should be possible, the speaker thought, to devise, with the help of the National Physical Laboratory, a standard oscillograph test. Many forms of artificial ear had been devised, chiefly for the purpose of investigating the characteristics of telephone receivers and to make voltmeter tests, as the use of the human ear for this was irksome to the subject and apt to be inaccurate owing to fatigue. As to the prescribing of a form of aid for a deaf person, the pure-tone method left something to be desired, as in this the rectifying property possessed by the human ear was left out of consideration. Hence a second harmonic might be heard by the patient more distinctly than the fundamental note. The photoelectric talking machine had great possibilities.

In the ensuing discussion stress was laid on the need to protect the public from commercial travellers who were selling aids for the deaf. The point was raised that possibly the use of aids for special occasions might cause the hearing of a partially deaf person to deteriorate.

Mr. W. M. MOLLISON read a paper on the

Operative Treatment of Vertigo

He said that such diverse causes as wax in the ear and an acoustic nerve tumour could give rise to the syndrome consisting of deafness, tinnitus, and vertigo. Therefore the first step in treatment was to make sure that the external and middle ear, including the Eustachian tubes, were normal. A neurologist should be asked to eliminate any central nervous lesion, not forgetting the possibility of migraine. Toxic causes should be searched for in tonsils, teeth, sinuses, and other sources, and attention should be paid to the possibility of syphilis. After these researches had been made there remained a group of patients, usually over 40 years of age, who had unilateral deafness of high degree, with tinnitus and vertigo. The vertigo usually came on in attacks which might last a few hours or a few minutes, often accompanied by vomiting and nausea, and hence this condition entailed great curtailment of normal activity. Mr. Mollison did not think it was always true, as sometimes stated, that vertigo ceased when the affected ear became quite deaf.

The most effective medical treatment to prevent these attacks was to give luminal orally, the dose being gr. ¼ once, twice, or even thrice a day. If the patient showed undue susceptibility to this drug, caffeine should be added. When drugs failed to relieve this crippling disability operation was justifiable. In his experience a simple procedure yielded good results. Fortunately one labyrinth only seemed responsible in most cases. Some years ago Mr. Sydney Scott had found that injection of absolute alcohol destroyed the labyrinth of the pigeon, and Mr. Mollison reasoned that the same substance might, if injected, destroy the function of the semicircular canals in man. He had therefore been injecting absolute alcohol through an opening in the external canal; 1 c.cm. of it was injected anteriorly in an endeavour to reach the vestibule. For from two to ten days thereafter the patient was very giddy, owing to the unbalanced action of the opposite labyrinth. In none of his cases had there been any sign of labyrinth infection. Twenty-eight of his 30 cases had been traced; 22 of them were cured of their vertigo, 3 were improved, while in 3 the vertigo was uninfluenced. He had carried out the same procedure in cases in which vertigo persisted after the radical mastoid operation. In these latter the old wound was reopened, and after thorough cleansing with ether, the external canal received the alcohol injection. To cover the hole in the canal, a temporal muscle flap was turned down into the cavity. Mr. Mollison only carried out this operation in cases of vertigo with deafness, and preferably in those whose deafness in the affected ear was of high degree, the opposite ear having good hearing. The procedure having no mortality, he argued that for these miserable patients it was fully justified. Among his guiding principles in selecting cases suitable for the operation were the exclusion of cases of middle-ear infection, especially mild Eustachian obstruction, and also of all cases of organic disease of the central nervous system, as well as those with otosclerosis, or with foci of infection.

Mr. W. THACKER-NEVILLE related the particulars of three cases in which he had employed the method just described. In the first no real giddiness remained, though the tinnitus was not improved, but in the other both vertigo and tinnitus were cured. The ages of his patients were 31, 40, and 55, the last was a woman.

Mr. SYDNEY SCOTT emphasised the necessity for accuracy in the injection, since during his pigeon experiments the bird died immediately when the alcohol was allowed to enter the vestibule. Alcohol spread and penetrated very quickly.

Mr. A. J. WRIGHT showed a case of aural vertigo in which he had injected alcohol through the oval window. The patient, a woman aged 52, had had left-sided tinnitus since she was 18. For five years she had had attacks of vertigo with vomiting, and once an epileptiform attack with loss of consciousness. On the left side she could hear conversation at 3 ft. distance. Under general anæsthesia he had injected 1 c.cm. of absolute alcohol by puncturing through the intact membrane and the footplate of the stapes. So far the procedure could be regarded as a success.

Mr. MUSGRAVE WOODMAN had been struck with the importance of Mr. Sydney Scott's work on the Eustachian tube; it was not sufficient to inflate that tube, one must be certain that air entered. In one case, a woman of 72 with giddiness to a distracting degree, who had refused any serious operation, he had punctured the drum. The small hole made remained open two months; for five years thereafter the patient was free of attacks of giddiness.

The PRESIDENT (Mr. Peters) was impressed by the method, particularly in cases in which the cochlea and the posterior semicircular canal were affected. It would be interesting to learn how far the alcohol penetrated.

A discussion took place on Saturday on two papers dealing with

Sinusitis and Infections of the Eyeball

Mr. E. R. CHAMBERS read the first paper, from the ophthalmological standpoint. He said that in many cases of eye trouble the nasal sinuses could be held responsible, though there might not be any obvious sinusitis. In dealing with these ocular infections, especially of the cornea, no time must be wasted, owing to the danger of the rapid supervention of visual defect. A few ocular conditions which did not respond to local treatment of the eye cleared up when the nasal infections had been dealt with. Conjunctivitis, chiefly affecting the lower lid, with little discharge but with itching and burning aggravated by bright light, dust, and wind, cleared up usually with simple ocular antiseptic treatment, but recurred as soon as that treatment was stopped. In some of those cases there arose a thickened velvety condition of the conjunctiva, and this was often due to nasal infection. Episcleritis, characterised by chronicity and recurrences, and often ascribed to rheumatism because of associated pains or neuritis, was usually the result of an endogenous sepsis, and generally a cure followed treatment of the sinuses or the elimination of the particular focus of infection. Any type of keratitis could be due to endogenous sepsis, but one kind was due more to sinus infection than to anything else; first only one eye was attacked and the condition remained localised for a time. Often the existence of the eye condition deflected attention from the prime cause, a septic focus possibly at a remote spot. In all such cases the sinuses should be investigated. Irido-cyclitis was due to a blood-borne infection, from sources outside the eye, and nasal sinus infection often played a large causal part in it. Retinal hæmorrhages and the presence of exudates were indications for investigating the sinuses. A suspicious happening was a sudden loss of central vision in young and apparently robust persons; these might disclose a small hæmorrhage at the centre of the retina, when in the speaker's view the cause was an endogenous infection often in the nasal sinuses or the teeth, the toxins of which had caused damage to the capillary wall followed by hæmorrhage. Finally Mr. Chambers spoke of a papillœdema of the optic nerve, in cases of which a swelling of 4 to 6 diopters might be present. With such marked swelling the suspicion of an intracranial condition might be entertained, but in this case it was unilateral, and there were no positive neurological findings. Often in these cases the sphenoidal sinus was implicated.

Mr. ERIC WATSON-WILLIAMS also emphasised the great importance of sinus examination in cases of failing sight, especially in young persons. The relationship could hardly be denied when the turning-point to recovery was treatment of the sinuses. The cases detailed illustrated three special points: the first was that often there was no manifest local evidence of infection. Patients whose noses were stuffed with polypi or were freely discharging pus, might be quite well in themselves with only local trouble. It was when local reaction was so slight as to attract no attention that toxic absorption seemed especially liable to occur, producing characteristic changes, ocular, nervous, or arthritic. In three of the five cases specially mentioned, rhinoscopy gave no result. The second point concerned the difficulty of excluding sinusitis on X ray evidence. In two of the five cases the report on the skiagrams was negative although sinusitis was discovered, and in two others the skiagraphic evidence was not borne out by the operative findings. The third point was the readiness with which the eye conditions yielded after the sinus disease had been dealt with, although the former had previously been intractable. Hence the reflection could not be avoided that early sinus treatment might have conserved the eyesight in many cases in which it had been damaged or lost.

The PRESIDENT (Mr. W. M. Mollison) said that there had not been presented to the meeting anything approaching mass statistics to show the frequency of the inter-relation between sinus and ocular disease. At Guy's Hospital the speaker had had many eye cases referred to his nose and throat department, but in a great number of them he had found nothing wrong with the sinuses, though every now and then he did find a diseased sinus. He asked why acute conjunctivitis was found in patients with antrum disease.

Mr. E. A. PETERS questioned the mode of extension in these cases, and referred to a case in which whenever the man blew his nose his lacrymal sac distended.

Mr. A. TWEEDIE referred to the importance of the degree of alkalinity of the culture medium when searching for organisms; sometimes no growth developed on a hyper-alkaline medium.

Mr. BROUGHTON BARNES spoke of a case in which, in a boy, the nasal swab bore *Staphylococcus aureus*; the boy died in six days of cavernous sinus thrombosis.

Mr. J. F. O'MALLEY said that the cases in which there could be no question of contiguity forced the conclusion that for the most part the relation of sinuses to ocular disability was one of a common endogenous infection. A circulating toxin tended to manifest itself at some time in the excretory organs; there might occur a glomerular nephritis, or a skin rash.

Mr. RITCHIE RODGER remarked on the frequency with which, in such cases as had been mentioned, the tonsils were at fault.

Dr. PAVY SMITH commented on the fact that the selected cases on which Mr. Watson-Williams's paper was based were all recent, and asked for a later report at a subsequent meeting, owing to the possibility of relapses.

Mr. JOHN PHILLIPSON spoke of the importance of making an exploratory suction puncture of the sinuses in all cases of discharging nose.

The session was concluded by a discussion on

Obstructions of the Trachea

Mr. LIONEL COLLEDGE, opening, said this subject showed great possibilities in the direction of errors of diagnosis and misdirected treatment. The causes of tracheal obstruction were divisible into extrinsic, compression of the trachea, and intrinsic, being diseases of the tracheal wall. In the former group were included mediastinal tumours, enlarged glands, and aneurysms, and, most important, goitres and cancers of the œsophagus. In benign goitre enough of the goitre should be removed to stop the pressure on the trachea. The real difficulty was the dyspnœa caused by malignant goitre, which was often accompanied by paralysis of the vocal cords and by œsophageal cancers. In malignant goitre cases, whether the cords were paralysed or not, no attempt should be made to perform tracheotomy. Crile's idea in such cases was to relieve the dyspnœa by a decompression operation, by division of the sterno-thyroid and sterno-hyoid muscles, thus allowing the tumour to expand outwards. As, however, these muscles were usually already invaded by the growth the suggestion was scarcely practicable. Sir Felix Semon long ago warned those doing tracheotomy for double abductor paralysis to be on their guard as they might encounter another obstruction lower down.

Diseases of the tracheal wall itself were rare; here might be encountered syphilis, tuberculosis, or new growths. Syphilis in the trachea, apart from that in the larynx, usually responded well to antisyphilitic measures, and the tendency to stenosis following such treatment in the larynx did not obtain in the trachea. Apart from tuberculous laryngitis, tuberculosis of the trachea was very rare, but one such condition he described in a man aged 56, who had pronounced tracheal stridor, with an immobile larynx. Below the cords, which were moving well, a grey swelling could be seen. Tracheotomy was done, but there was much granulation tissue, and the patient had difficulty in getting rid of the large plugs of material. No kind of medication seemed to give much relief. Accordingly the affected part of the trachea was removed, and it gave astonishing relief. Tuberculosis bacilli were easily demonstrated.

Primary tumours of the trachea were very rare. Mr. Colledge described a case in a waiter, aged 37, who had a tracheal carcinoma and was treated by endoscopic methods. The man breathed freely through the tube, and his voice was almost normal. He remained well for ten years, and was able to continue his work. Then he had a recurrence of the obstruction and drowned himself. In many of these cases the first diagnosis was asthma. He related cases in which the tumour was made to shrink by the repeated application of deep X rays.

Mr. F. C. ORMEROD related a number of instructive cases of tracheal obstruction, and concluded by showing skiagrams to illustrate the ingrowth of malignant tissue direct from the upper lobe of the lung through the wall of the trachea. Such a growth, he said, originated in a small upper lobe bronchus, and often reached the lumen of the trachea by direct infiltration before emerging from the main upper lobe bronchus.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY

AT the last meeting of this society, held in Newcastle-upon-Tyne, Mr. WILLIAM HUNTER read a paper on the *treatment of the post-hæmorrhagic state*. He defined it as "that state which follows the rapid loss externally of a quantity of blood sufficient to give rise to symptoms and signs," and said his object had been to evolve a practical routine for early emergency treatment. Here the aim was to restore a normal efficient circulation and so get rid of the anoxæmia; the capillary walls must be brought back to their normal state and metabolism must be accelerated to restore the functions of the various organs of the body. The treatment adopted consisted in intravenous infusion of glucose-gum solution (at the rate of 30 to 40 minutes per pint) with intramuscular injection of insulin, allowing 1 unit of insulin for every 3·0 g. glucose; ephedrine hydrochloride in 1-grain doses was found most efficacious for raising the blood pressure. After this emergency treatment, blood transfusion employing the citrate method was advisable. Cardiac and circulatory stimulants were not found to be of great value.

Mr. HARVEY EVERS and Mr. FRANK STABLER reported two cases of *severe dysmenorrhœa associated with protein sensitivity*. In the first case dysmenorrhœa accompanied by giant urticaria was ushered in by vaccination. After carefully testing the cutaneous sensitivity to various protein products, it was found that the patient was sensitive to wheat. Exclusion of this from the diet cured the condition.

Dr. E. FARQUHAR MURRAY read a paper on *radium treatment for gynæcological conditions in the Newcastle Centre*. He traced the history of radium treatment in the gynæcological department from 1920, and said that since 1932 this treatment had been intensified and operation had been abandoned in cases of carcinoma of the cervix. The Stockholm technique had been employed, and the results were as follows:

1930	..	..	50 per cent.	alive after	4	years
1931	..	..	53 ,,	.. ,,	3	,,
1932	..	..	82 ,,	,, ,,	2	,,
1933	..	..	81 ,,	., ,,	1	,,

The results in women over fifty had been very good; the treatment of recurrences was discouraging. For some years radium had also been used for all cases of carcinoma of the body of the uterus, and the general improvement obtained had been favourable to continuance, several cases having passed a three-year period without trouble. Upper vaginal growths had followed the course of cervical lesions; lower vaginal growths gave disappointing results. Vulval growths did not seem to respond to radium treatment to any extent, and the tendency had been to excise them wherever possible and to use diathermy for those which were definitely inoperable.

REVIEWS AND NOTICES OF BOOKS

Method of Action of Radium and X Rays on Living Tissues

By HECTOR A. COLWELL, M.B., Ph.D., M.R.C.P., D.P.H., The Barnato Joel Laboratories, Middlesex Hospital. London: Humphrey Milford, Oxford University Press. 1935. Pp. 164. 15*s*.

IT is a pleasure to welcome in book form the essay which was awarded the Garton prize and gold medal of the British Empire Cancer Campaign, 1934. Dr. Colwell has assembled the experimental evidence accumulated by many workers over a long period, has added to it the results of his own experimental work, and has produced an authoritative account of the chemical and general effects of radiation on living tissues which is at the same time a work of reference and a stimulus to further study.

In an introductory chapter he recapitulates the accepted teaching on the chemical and physical structure of the cell as shown by micro-dissection, chemical analysis, or special staining methods. He then proceeds to show the proved effects of radiation on the cells whose structure he has described, beginning with changes in the viscosity of colloids, and the oxidation and reduction phenomena which may be related to metabolism in living cells. The texture of the argument is close, and to appreciate it fully a considerable knowledge of the chemistry of proteins and the interactions of enzymes both in normal processes and in autolysis are necessary; but the fact is made quite clear that doses of radiation within the limits of those used in therapy definitely affect the cell constituents both chemically and physically, and that the most important changes occur in the nuclear and cell membranes. Of particular interest are the references to the author's own work in collaboration with R. J. Gladstone on the effects of X rays on developing chick embryos and on rat liver. They were able to demonstrate the partial, or even complete, disappearance of the divisions between the cells, sometimes with the formation of a syncytium, and this gives histological support to the chemical evidence of a special action which is increased by the presence of certain elements, such as copper or silver in colloidal form.

Immunity reactions are subjects of controversy; many opinions are quoted of which the results are discordant, and no conclusions are reached. On the other hand, resistance to tumour growth as a result of the inoculation of fragments of irradiated tumour, as shown in the experiments of S. Russ, H. Chambers, and G. Scott, is accepted as an important observation. The suggestion is that a substance inhibiting tumour growth is obtained at a definite point in the autolysis of tumour cells. This reaction does not appear to be peculiar to the autolysis following irradiation, as it has also been produced by cutting off the blood-supply of Jensen rat sarcoma for a definite length of time, just enough to allow of the development of the transitory inhibitory substance without the more complete destruction of the cell which carries with it the release of a stimulating substance. It is pointed out that the very transitory and uncertain changes make it difficult to imagine that this resistance can be hoped for as a result of the irradiation of clinical tumours.

The action of radiations on malignant growths remains a subject of considerable difficulty, particularly when the treatment of human cancer is referred to. The confusion of terms and the different methods of calculating dosage used by different workers make their observations difficult to collate. The gross changes are well known, and there is much of interest in the histological studies detailed, but they would be of greater value could we be certain that the tissues received a reasonably homogeneous radiation of measured intensity. Much stress is laid on the lethal dose as determined by the disappearance of tumours in vivo, or the amount of radiation necessary to prevent a tumour radiated in vitro from taking when inoculated into a fresh host. This is undoubtedly an important method of determining dosage, but it is to be hoped, in view of the discussions on the unit of dosage, that Dr. Colwell will at some future date summarise the effects of doses measured by physical methods.

The questions of wavelength and of relative sensibility are discussed, and the view of Russ and Scott that the relative radiosensitivity of skin and tumour tissue may be reversed by different wave-lengths is quoted as a valuable practical contribution. Throughout the book the practical aspect of the subject is emphasised, and the need for experimental radiology is made increasingly clear. There is an excellent bibliography, and the book is well printed in clear type.

A Manual of Diseases of the Eye

Seventh edition. By CHARLES H. MAY, M.D., and CLAUD WORTH, F.R.C.S. Eng. Extensively revised by MONTAGUE L. HINE, M.D. Lond., F.R.C.S. Eng., Surgeon to the Royal Westminster Ophthalmic Hospital. London: Baillière, Tindall and Cox. 1934. Pp. 505. *15s.*

THE revision of the text has been very efficient in this edition. Though there is a good deal of new matter concerning modern developments such as the orthoptic treatment of squint, and the operative treatment of detached retina, some of the chapters contained in recent editions, such as Mr. Devereux Marshall's chapter on colour vision and Mr. S. H. Browning's on vaccine treatment in ophthalmology, have been curtailed, so that the size of the volume has not been materially increased. In the chapter on detached retina there is a new coloured plate depicting a very evident tear in a large detachment. The student must not expect all his cases to be so easy to diagnose with the ophthalmoscope. The most modern methods of treatment by diathermy, according to the methods of Larsson and Safar, are referred to but a full description of them is beyond the scope of such a work as this. The illustrations, which have always been a feature of this work, now number 350, including those on 25 coloured plates. This in itself should commend the book to students.

Human Stupidity

A Short Introduction to the History of Human Stupidity. By WALTER P. PITKIN. London: George Allen and Unwin Ltd. 1935. Pp. 574. *12s. 6d.*

Mr. Pitkin has written an important and arresting book on Stupidity which, he maintains, is the fly in the ointment of our civilisation and has always been so. He has little respect for physical "toughness." "Those very powers of resistance," he says, "which pulled us through the bitter half million years contributed much to the dulness and general slow wit of the race. Yesterday's virtue has become to-day's evil." This is only one of many striking and challenging observations in this exhaustive, though never exhausting, book. "For half a million years the typical man at his best was a child's mind with a youth's outlook on life. Being on the whole poorly nourished, his behaviour approximated that of a poorly nourished adolescent." The causes of our stupidity are apparently legion, ranging from heredity to hookworm. It is stupidity which makes even the physically strongest of us submissive and so leads to war. "Not all the discoveries and inventions of mankind since the close of the Pleistocene age have benefited the race as extensively or as intensively as the war morons and war maniacs have harmed the race." The book ends on an optimistic note. Thanks to science, "for the first time in the career of mankind superior intelligence can wholly dispense with the aid of the dull and the otherwise inferior." Altogether this is a most entertaining book full of facts, figures, and daring—sometimes too daring—deductions. Though denunciatory in the extreme, Mr. Pitkin writes with kindliness and humour rather than with bitterness.

The Carbohydrates

Fifth edition. By E. F. ARMSTRONG, D.Sc., F.R.S.; and K. F. ARMSTRONG, M.A., B.Sc. London: Longmans Green and Co. 1934. Pp. 252. *15s.*

THAT highly respected work "The Simple Carbohydrates and the Glucosides" first appeared in 1910, but after the appearance of the fourth edition in 1924 *it* underwent binary fission into "The Glycosides" (1931) and the present volume. The latter provides a condensed and readable account of the important information available on an interesting group of the organic compounds. Just as some of the greatest music was produced under the rigid restrictions of the sonata form, so nature has produced some of her most useful substances by the arrangement of 6 carbon, 6 oxygen, and 12 hydrogen atoms whilst adhering to rigid rules of valency and some arbitrary configurations. The study of the simple sugars is not merely a study of permutations, solid geometry, and organic chemistry; most absorbing is the consideration of why only certain of the possible compounds have been selected to appear in the plant and animal world. The medical reader will be amazed at the rapid progress in our knowledge of the structure of the carbohydrates. Starting from the establishment of the molecular configuration of the two ring types of glucose it has been possible to develop with great accuracy and detail the actual configuration of the higher saccharides. The structure and spacial configuration of the disaccharides and oligosaccharides have now been worked out and even the higher polysaccharides are yielding their secrets. In this book a most difficult subject has been clearly presented and the references are accurate and remarkably complete.

British Journal of Children's Diseases

To the April–June issue (vol. xxxii.) Dr. E. Ashworth Underwood contributes the first part of a paper on the Neurological Complications of Varicella. He reports a case of his own and reviews 119 others which he has collected, together with 23 which are often quoted but which he discards. He adopts the classification of Berode and Miget, which consists of a group of prodromal symptoms, and six other groups—viz., meningo-encephalitis, encephalitis, myelitis, neuritis and polyneuritis, ocular manifestations, and "other conditions."—In continuation of his analysis of Over Four Thousand Cases of Educational Deafness, Mr. Macleod Yearsley deals with doubtful cases, of which there were 105 in his series, and deformities of the external ear, of which there were 22. He then discusses the prevention of congenital and acquired deafness. The causes of the acquired cases of which there were 2787 were as follows: diseases of the nervous system 382 (13·6 per cent.), infectious diseases 967 (34·7 per cent.), and primary ear diseases 1438 (51·5 per cent.). The principal infectious diseases responsible for deafness were scarlet fever, measles, and diphtheria in the order named.—In a paper on Cancrum Oris in Ancient Rome, Dr. W. J. Rutherfurd refers to the description of this condition by the poet Martial, and the various local remedies recommended by Celsus for faucial ulceration and cough in general. In a postscript the editor remarks that the diagnosis of cancrum oris in Martial's epigram—which has been made among others by Ménière and Raymond Crawfurd—is much more likely than that of tertiary syphilis which was suggested by Buret. The abstracts from current literature are devoted to acute infectious diseases.

THE LANCET

LONDON: SATURDAY, JUNE 22, 1935

A DIPLOMA IN ANÆSTHETICS

SINCE specialisation is a necessity of modern medicine, it is good that the public should be able to learn whose training and experience has made him an expert deserving recognition as such. The issue of special diplomas helps to make a rarer phenomenon of the sort of amateur specialist who is a danger to the public as well as an unfair competitor with the practitioner of all ranks. The arguments in favour of such diplomas are forcible, though many members of the medical profession feel that the institution of each new one implies yet another encroachment upon general practice. Of the two diplomas recently instituted by the English Royal Colleges, in child health (D.C.H.) and in anæsthetics (D.A.) it is the latter which is more likely to give rise to misgivings, since there are firms where one of the partners acts regularly as anæsthetist in circumstances arising out of the conduct of the practice, save where the nature of the case or the wishes of one of the parties concerned demands a specialist. It would be embarrassing to a surgeon in the habit of working with a particular anæsthetist to receive a suggestion that in the place of his usual coöperator in the district he should obtain the services of one whose ability is guaranteed by the new affix, but whom he may never have worked with. There are districts of considerable importance where practitioners have secured among their colleagues a sound reputation as anæsthetists. In fact the combination of general practice with specialisation in anæsthetics is a very usual one even in the large towns, and has advantages from every point of view. It would be calamitous, therefore, if the attitude were to be adopted that it is a dereliction from duty on the part of the practitioner or affection on the part of the relatives to summon anyone without a special diploma to give an anæsthetic. On the other hand, it often happens that a surgeon operating away from his usual neighbourhood has to take on trust the services of an anæsthetist whom he has never heard of; and it will be not only a great relief to him but a notable advance towards the reduction of operative risks to have spread throughout the land a number of practitioners on whom surgeons can rely with confidence for satisfactory service in anæsthetics. The particular diploma under consideration is not so constructed as to select only the super-anæsthetist. On the contrary the examination and credentials which qualify a candidate for the distinction are of such a kind that every competent anæsthetist of fairly wide experience should be able to pass the test imposed. This seems to us to be the right principle to follow in setting up a diploma in a subject where practice counts so much more than theory.

We publish elsewhere in this issue a list of ten well-known anæsthetists who have been awarded the diploma, without examination, under conditions detailed on p. 1479. In the future examinations will be held twice yearly, in May and November. The tests will be written and oral, and the subjects include history, theory, and practice of anæsthetics; pharmacology and elementary chemistry of anæsthetic drugs; and pre- and post-operative conditions relevant to anæsthesia. A candidate for entrance to the examination must either have held a resident appointment in a recognised general hospital for twelve months, of which at least six shall have been as resident anæsthetist, or else he must have administered anæsthetics in a hospital on not less than one thousand occasions, at least one-half of which shall have been for major surgical procedures. The above conditions may be modified, it is stated, for candidates who have carried out original investigations in the science or practice of anæsthetics or whose studies have been extended over a long period without fulfilling the exact conditions.

The D.A. is an interesting innovation, for it is the first of its kind in any land. It is fitting that it should originate in this country, for the English-speaking nations may legitimately claim to have led the world in all that pertains to general anæsthesia. In them almost exclusively is to be found a body of practitioners who devote their professional lives entirely to the administration and teaching of anæsthetics. The importance of this branch of work from the point of view of safeguarding human lives as well as from that of the assurance of the best possible results following surgical operations needs no demonstration, but it has been slow of recognition. Even in the land of SIMPSON, SNOW, HEWITT, and DUDLEY BUXTON, anæsthetists are only now beginning to get the consideration which their influence on the welfare of patients amply demands. In continental countries the recent formation of societies of anæsthetists, with associated official journals, shows that abroad also the Cinderella of medical specialties is beginning to reach a position equal to that of her elder sisters. The growing popularity of regional and local methods and of basal narcotics should mean not the curtailment of the general anæsthetist's activities, but the enlargement of his scope, and an increasing appreciation of the need for expert handling of the many new methods of making the patient insusceptible to pain impulses.

UNDULANT FEVER

UNDULANT fever is now recognised as an endemic disease in almost every country of the world. The primary reservoir of infection is in animals, and it is from animals that infection is transmitted, directly or indirectly, to man. In countries where goats and sheep are common, the main type of infecting organism is *Brucella melitensis*; in countries with a predominant cattle population the corresponding organism is *Br. abortus*; while the porcine *abortus* type, sometimes referred to as

Br. suis, seems to be confined almost entirely to the large hog-raising districts in the middle-western states of North America. During the past few years several reports have been published assessing the probable incidence of undulant fever in different countries. The difficulties of obtaining accurate information on this point are very great, partly because undulant fever is not generally a notifiable disease, partly because active infections with brucella are often atypical, and partly because an exact diagnosis can be made only on bacteriological grounds. In this country, where the disease is not notifiable and bacteriological examination of pyrexial cases is not undertaken as a routine, the number of collected cases must obviously be inferior to the real number. In countries such as Denmark, on the other hand, where the blood of pyrexial cases from all over the land is sent in to one central laboratory at Copenhagen, a much more accurate assessment can be made of the real number of active brucella infections. Dr. GUNNAR OLIN, who has just produced an extraordinarily valuable monograph on undulant fever in Sweden,[1] gives the following figures for the annual incidence of this disease during the five-year period 1929–33: Germany 8·3, Sweden 18·4, and Denmark 150 per million of the population. The much higher figure for Denmark is partly due to the larger number of cattle and the wider distribution of contagious abortion, but is undoubtedly ascribable largely to the centralisation of laboratory control and the facilities afforded, even in country districts, for adequate bacteriological examination.

Bearing these points in mind, it is interesting to consider the figures given in another part of our issue by Dr. BEATTIE, Dr. SMITH, and Prof. TULLOCH for the incidence of undulant fever in Scotland. By private investigation, and through information supplied by the Scottish Department of Health, they have been able to collect records of 97 cases of undulant fever occurring since 1930—an average incidence of some 20 cases a year. For reasons similar to those just discussed, it is certain that this incidence underestimates the true incidence of the disease. It is noteworthy, for example, that the collected cases occurred around centres where bacteriological investigation of the disease was being carried out, and that the incidence among doctors and nurses was considerably greater than that justified by the ratio they bear to the total population. These findings are very similar to those in England and Wales in showing that the number of cases detected is in proportion to the frequency of bacteriological examination. Thus the apparent incidence is greater in towns than in country districts, because laboratory facilities are more readily available in urban areas, and it is greater in doctors than in other occupational classes, because doctors suffering from undiagnosed pyrexia insist on a proper diagnosis being made.

With regard to the route of infection, the Scottish investigators are again in agreement with the conclusions reached by numerous workers in other countries. Only 14 out of their 97 patients had any direct contact with infected animals, and it is these patients alone that are likely to have been infected through the skin. The remainder had probably been infected by consuming raw milk or cream. Though contagious abortion is known to be widely distributed among the cattle of Great Britain, and though it has been shown that about 30 per cent. of samples of raw milk retailed throughout the country contain living *abortus* bacilli, doubt is not infrequently cast on the milk-borne origin of undulant fever in man. It is asserted that, if milk was responsible for infection, there ought to be a much closer relationship than apparently exists between the per-caput consumption of milk and the frequency of undulant fever. To those who are ignorant of the complexities of epidemiological inquiry, this argument is undoubtedly attractive, but it requires little knowledge of the distribution of human and animal disease to realise that such arguments are often fallacious. It is known, for example, that the malarial parasite is borne by anopheles mosquitoes, but numerous surveys in different countries have failed to show a direct relationship between the prevalence of anopheles and the incidence of malaria. The carriage of malarial parasites by anopheles, or of *abortus* bacilli by milk, is merely one of the factors that finally determine whether a given person shall or shall not develop clinically evident disease. The size of the dose, the frequency of the dose, the time intervals between successive doses, the immunological state of the patient, his past experience with the infecting agent, physiological and hygienic conditions at the time—these and doubtless other factors probably all play a part in determining the outcome of an infection. What is far more important than the quantity of the milk is the quality of the milk consumed in relation to the incidence of the disease. On this point the available figures are very suggestive, showing that in towns where most or all of the milk is pasteurised undulant fever practically does not occur. The few cases that have been observed in London, for instance, where about 95 per cent. of the milk is pasteurised, have been traced to raw milk. Among the Scottish cases, it may be noted, there were four patients who consumed large quantities of raw milk for medical reasons. It is pointed out that when practitioners order a milk diet for their patients they should insist that the milk should be pasteurised or boiled.

Dr. BEATTIE and his collaborators are silent on the treatment of the disease. Considering the seriousness of undulant fever in the individual patient, it is time that an inquiry was set on foot to discover some useful form of treatment. Ordinary vaccine therapy has, on the whole, proved very unsatisfactory, nor have chemotherapeutic measures justified themselves. The use in the United States and in certain European countries of melitin or abortin has apparently met with a limited success, but very little exact information on the results is obtainable. In Italy intravenous vaccine inoculations are being advocated, the intention being to provoke a severe constitutional reaction similar to that in ordinary protein shock therapy. Fortunately the case-mortality of the disease does not usually exceed 3 or 4 per cent., and except in persons suffering at the same time from some other condition it is usually safe to give a favourable ultimate prognosis. This in itself is encouraging both to the patient and his relatives in a disease whose average duration is about three months.

A CHILDREN'S IMMUNOLOGY CLINIC

At the Rome Hospital Congress, of which a brief account was given in our last issue (p. 1397), Dr. A. F. **Cooney** spoke of a change in the attitude of public health authorities with which the hospitals in their area would have to reckon. Hitherto, he said, the advice of the hospital had usually been sought for illness. Now local authorities are seeking its aid in the prevention and preventive treatment of disease. Dr. **Cooney** is secretary of the Irish Hospitals Commission and although he expressly stated that the views he was ventilating were his own it may be taken that the tendency is clearly to be seen at Dublin hospitals. Since he spoke a hospital in London has announced an excursion into preventive medicine, which has perhaps no parallel in England. On Thursday evenings and, if necessary, on Saturday mornings, an "immunology clinic" at the Hospital for Sick Children, Great Ormond-street, will undertake Schick, Dick, and Mantoux tests, skin tests applied in hay-fever and other allergic conditions, as well as active or passive immunisation against diphtheria, scarlet fever, and measles, and the treatment of diphtheria carriers. The departure will provide an opportunity to obtain experience now lacking in many different directions. The inclusion of vaccination against whooping-cough indicates, we hope, an attempt to find by controlled investigation on a large scale which, if any, of the several vaccines described in the literature is effective, and in what dosage. The position is different in regard to convalescent measles serum, for here the value is well recognised, it is the supply which is failing.

Seven years ago, acting on a suggestion from the Ministry of Health, the Ormond-street Hospital prepared this serum on a scale sufficient to supply a certain number of institutions and private practitioners. At the present time the supply is very limited and the hospital is urging practitioners to persuade adult patients who have had measles within the last few years to volunteer as donors, during the non-epidemic periods, and so avoid the rush which is bound to occur when measles again becomes epidemic. The efforts of the London Fever Hospital and the Oxford medical authorities, for example, are already securing a harvest by no means negligible, but it is probable that a campaign as energetic as the anti-diphtheria propaganda in New York, or the devoted work of those who have built up the magnificent blood-transfusion service in London, would discover in the community further supplies of convalescent measles serum, or the less efficient but useful "adult serum." But a vigorous campaign by some organisation such as the British Medical Association or the Society of Medical Officers of Health will be needed to achieve an adequate general supply of this life-saving material for ill or very young children. We note with pleasure that the B.M.A. Council is to ask the representative body of practitioners to urge on local authorities the establishment of adequate machinery for the collection and storage of convalescent serum. Is it too much to hope that the clinic may help to solve another problem ? D'**Arcy Hart**'s figures show that of every 100 city children aged 7 apparently non-tuberculous 30 are positive to the Mantoux test. What we urgently need to know is this—which group will show in later life the greatest incidence of disabling tuberculosis, the 30 positive or the 70 negative ? Then it may be possible to take precautions for the safeguarding of the more susceptible child.

ANNOTATIONS

HUMAN STUPIDITY

"Gegen Dummheit kämpfen die Götter selbst vergebens."

Is there a stupidity that shapes our ends ? Mr. Walter P. Pitkin thinks there is and has written a book, reviewed elsewhere in this issue, to prove it. This book is some 200,000 words long and is called, perhaps in irony, "A Short Introduction to the History of Human Stupidity." In it Mr. Pitkin attempts to sustain the novel thesis that civilisations and cultures are moulded not by those of outstanding ability but by the stupid who, it seems, are always in the majority. By stupidity we are to understand, among other things, "a lack of sensitivity," "a state of confusion and low velocity" (presumably mental), or "an inability to cut through to the heart of a situation or problem." Very few of us will be able to escape conviction on one or other of these counts. In the bad old prehistoric days, according to Mr. Pitkin, it was only the stupid, that is, the relatively insensitive, who were able to survive the rigors of life on this planet. Hence, he argues, our ancestors were the clods of humanity and we are the children of clods unto the nth generation, including, of course, Mr. Pitkin himself as, to do him justice, he would be the first to admit. Thus stupidity persists as the supreme social evil. In fact, to such depths of stupidity have we sunk that the tail wags the dog. However comparatively sensible some of us may be there is, apparently, a ten-to-one chance against even the most intelligent of us acting intelligently in any given set of circumstances. Mr. Pitkin has collected a formidable array of facts all, doubtless, authentic. But some of his deductions from these facts are not by any means acceptable to those with special knowledge. A mere doctor, for example, might agree that "the woman who frequented a beauty-parlour where she was rolled and pounded in an attempt to keep slender" was essentially stupid. He might be sorry to hear that she subsequently developed cancer of the hip. But if he accepted the deduction, as Mr. Pitkin appears to do, that the former folly caused the latter catastrophe, he would be proving Mr. Pitkin's main thesis of human stupidity rather than the causative relation suggested.

Many of Mr. Pitkin's denunciations of historic acts of stupidity are doubtless well-merited. It is, however, proverbially easy to be wise after the event more especially when one is in full possession of the facts and can see them with detachment and in retrospect. Nor is it always just to condemn an act as stupid having first removed it from its proper context in time and space. No doubt, for example, the *Titanic* disaster should not, and need not, have occurred but it is manifestly unfair to condemn the stupidity of the wireless operators for paying too little regard to ice-warnings when they were, in common with their superiors, bent on making a record trip. Nobody expects a big ship to sink on her maiden voyage. Are we to be called stupid if we fail to make sure that the spokes of our car-wheels are sound every time we drive it? A surfeit of caution may be just as ludicrous as the lack of it may be disastrous and probably few men, except perhaps postmen, think it worth while to insure their trousers against dog-bites.

Nevertheless Mr. Pitkin's book is a slashing indictment of human behaviour not to be lightly dismissed. No nation or calling seems to have escaped his whip except, perhaps, the profession of medicine. It is difficult to see why this invidious distinction should have been made unless it be that the author felt that the balance of stupidity lay with the patient rather than the doctor. Much of what he has to say rings uncomfortably true. In spite of all, he remains an optimist and a constructive one at that. Nothing, he thinks, will be accomplished by religion, nor by moral drill, nor, least of all, by laws. Science will save us. His prophecy of an Utopian world saved from stupidity by science makes cheerful reading and it is a tribute to his book that we recommend the average *laudator temporis acti* to stop and buy one.

VARIETIES OF TUBERCLE BACILLUS

In recent Annals (January–February, 1935) of the Pasteur Institute is presented an exhaustive study, illustrated with more than one hundred excellent photographs, of the morphological, cultural, physical, and pathogenic properties of the three main types of tubercle bacillus. Dr. K. Birkhaug was formerly associate professor of medical bacteriology at the University of Rochester school of medicine, and has for the past three years been a member of the Paris Institute. In each of the nine strains investigated, Dr. Birkhaug found on culture three different kinds of colony: "R" (rough), "S" (smooth) and "Ch" (chromogenic), using the Petroff nomenclature. By means of single-cell cultures he shows that each of these three dominant varieties of colony is interconvertible in vivo as well as in vitro and that none of them possesses invariable characteristics, whether physiological, biochemical, physical, or pathogenic. The "Ch" and "S" varieties of both avian and mammalian tubercle bacilli, however, differ essentially from the "R" variety in their "diphasic" development in liquid synthetic media containing glycerin; this is characterised by an initial diffuse growth throughout the medium, in the manner of *B. coli*, with a clarification of the liquid in the course of one week and the formation of a flat and creamy surface film—in striking contrast with the "R" variety, which presents a "monophasic" surface growth only. Similar differences exist in the pH curves in liquid media inoculated with the three varieties of colonies, the mammalian "S" and "Ch" varieties producing an acid reaction in the course of eight weeks, and the "R" variety a neutral or alkaline reaction. With the avian "S" and "Ch" varieties an alkaline reaction curve is produced, while the avian "R" variety acidifies the medium. The electrophoretic mobilities of the "S" and "Ch" varieties, both of avian and mammalian origin, are definitely slower and more uniform, irrespective of age of culture, than those of the "R" variety which are nearly twice as rapid and variable with the age of the culture. Differences also exist between the three varieties in agglutination by acid, in resistance to heat, disinfectants, dyes, light, age, and unfavourable nutritive conditions. But the chief interest lies in Dr. Birkhaug's conclusions on the pathogenicity of these varieties of bacilli. The "Ch" variety, irrespective of its origin, is avirulent for the laboratory animals. The avian "S" variety is exceedingly virulent for the hen and rabbit, while the "R" avian variety is relatively avirulent for these animals. The mammalian "S" variety is relatively virulent for the rabbit, guinea-pig, and hen, injected intravenously or intraperitoneally; with passage the virulence is rapidly lost. On the other hand, the mammalian "R" variety is dominantly virulent for the laboratory animals, producing progressive and generalised tuberculosis, the human "R" variety only in the rabbit, the bovine "R" variety both in the guinea-pig and the rabbit. The "R" variety of the Calmette-Guérin bacillus (B C G) is relatively avirulent for laboratory animals, unless excessively large doses (10–50 mg.) are injected, intravenously or intraperitoneally, when typical tubercles result showing a tendency to caseation and early absorption. The "S" variety of B C G has shown an initial relative virulence in the rabbit and guinea-pig in doses of 1–10 mg. of the first and second passage cultures. The same doses injected subcutaneously produce localised caseous spots which always heal by ulceration or calcification. This virulence of the "S" variety is manifest only with intravenous or intraperitoneal injection. Miliary tubercles are produced in the lungs, liver, spleen, and occasionally in the kidneys and joints. After two passages cultures of the "S" variety rapidly lost their initial virulence, and during 31 bi-weekly passages on artificial media the "S" variety remained constantly avirulent for laboratory animals. Whether or not the "R" and "S" varieties of the B C G will always remain relatively avirulent Dr. Birkhaug admits is beyond current prophecy.

THE NORMAL HAND

The hunt for the "normal" is pursued in diverse ways by many people, who find a common difficulty in providing a definition of the term. Since it is essentially a question of fixing arbitrary standards of limits of variation, and gathering within these limits a large number of individuals, it is not surprising that the results of different observers do not agree in every particular. Nor does it matter overmuch. A normality in this sense is only a record of the greater frequency of the character in question among the individuals investigated. Prof. F. Siegert has chosen his material very carefully in his "Atlas der Normalen Ossifikation der Menschlichen Hand."[1] He has eliminated pathological influences, has examined histories, and has taken into consideration height and weight with reference to age. He has, in fact, taken only the best in all these sub-classes, and has made from them a group which he claims, with apparent justice, to be worthy of the term "normal." If the physiological processes are here shown to go on within narrower limits than is commonly thought, this is because to be of any practical value a rule must be definite enough to allow of measurement of variations from it. Probably if similarly well-grouped observations are made in this country it will be found that there are certain points of difference, but this possibility does not lessen the value of the records which we owe to the author of this work. Thirty-six plates of photographs, covering 150 children of both sexes (contrasted), go with the book as illustration of the material. It provides a definite standard for which, whether or not it will be found to apply to us, Prof. Siegert deserves our appreciative thanks.

ANOTHER MEDICAL VICE-CHANCELLOR

THE appointment of Mr. H. L. Eason as vice-chancellor of the University of London brings a medical man again to this high office after a period of 11 years. The last medical vice-chancellor was Sir Holburt Waring, whose tenure was between 1922 and 1924. Mr. Eason will bring to his duties an enthusiasm which has survived a vast experience in the public service—academic, medical, and social. At Guy's he has filled for 15 years a dual rôle, being a member of the honorary staff as ophthalmic surgeon, and also medical superintendent of the hospital. He is a representative of the University of London on the General Medical Council and its junior treasurer, and a representative of the Ministry of Health on the General Nursing Council. He is a coöpted member of the hospitals and medical services committee of the L.C.C., a member of the council of the British Hospitals Association, and a member of the general council and economy committee of the King Edward's Hospital Fund for London. He is also a member of the governing body of the British Postgraduate Medical School and of its school council. These are only some of his present activities. It would be difficult to enumerate the diverse committees on which he has served in the past, and impossible to over-estimate the value of his judgment in expediting non-controversial business and of his acumen in defining crisply the important issues. Mr. Eason has represented the medical faculty on the senate of the University for a quarter of a century, and has been a regular attendant at its meetings except for the four years of his war service as consulting ophthalmic surgeon to the forces in the Mediterranean and Egypt. It is thus a trusted friend and a wise counsellor who has been elected, and it is pleasant to think that his term of office will coincide with the centenary of the foundation of the University in 1936 and with its installation in a permanent home.

MANUAL REMOVAL OF THE PLACENTA

FROM the opening of the department of obstetrics at the Johns Hopkins Hospital in 1896 to June, 1933, there were 186 cases in which manual removal of the placenta was performed following delivery of a viable child. C. H. Peckham [1] states in a statistical survey of these cases that the incidence of the operation worked out at 1 in 120 patients, which compares with 1 in 312 (B. C. Hirst, 1918), and 1 in 110 (H. Montag, 1926). Most of the patients who had to have their placentas removed manually were multiparæ, and the incidence was highest among those whose labour had been prolonged as a result of sluggish uterine contractions. Premature labour also appeared to conduce to an abnormally adherent placenta. In 67 of the patients there had been spontaneous delivery, manual removal of the placenta being the only manipulation. Of these as many as 32 (48 per cent.) developed a puerperal infection and 7 died. These figures are more depressing as regards infection even than those published by A. Bourne (1921) or H. Baumm (1921) each of whom found an incidence of sepsis to be about 35 per cent. Peckham notes that manual removal has been less frequently performed at the Johns Hopkins during the later years of the period under review and ascribes this in part to a more real appreciation of the dangers attendant upon it. Of the indications for manual removal, hæmorrhage is the most obvious; mere retention of a placenta in utero, in the absence of hæmorrhage, should not be regarded as a condition demanding interference for at least two hours after delivery. By his emphasis on the danger associated with an intra-uterine manipulation which in itself may be a very simple one Peckham has shown once again the need of a searching inquiry into the factors that govern defective contractions of the uterine muscle.

JULES GONIN

THE announcement of the death at Lausanne of Prof. Jules Gonin at the early age of 64 is a reminder how recent is the modern treatment of detachment of the retina. Until 1930, when Gonin was invited to read a paper at the Oxford Ophthalmological Congress, his name was scarcely known in this country and his operation had only been performed by a few enterprising surgeons at Moorfields or elsewhere. Now his name is known to everyone, and although the particular technique that he advocated, and himself continued to practise, has been to a large extent superseded by newer and—according to the experience of most English operators—improved methods, his main contention, that the secret of successful treatment lies in sealing up the communication between the vitreous chamber and the subretinal space, remains unshaken. Gonin's operation or one or other of its modifications is now part of the ophthalmic surgeon's equipment, to the great benefit of most sufferers from the malady whose symptoms are at all recent. The results of treatment in retinal detachment of various types are to be discussed at the coming Oxford Congress in July. Gonin, although preferring his own technique, was by no means blind to the possibility of improvements; this comes out clearly enough in a monograph reviewed in these columns a few weeks ago (Jan. 19th, p. 154). There will be general regret that this congress must forgo his presence and the benefit of his ripe experience.

THE NEW WESTMINSTER HOSPITAL

ON Wednesday next, June 26th, the Prince of Wales will lay the foundation-stone of the new Westminster Hospital which is to be erected on two sites east and west of St. John's-gardens on the south side of Horseferry-road, not far from Lambeth Bridge. On the west side of the gardens will be the nurses' home and the medical school; on the east side the hospital proper. A beginning is to be made with the nurses' home which it is hoped to have ready for occupation next year, after which the building of the main hospital will be begun. The home is to accommodate 40 sisters, 200 nurses, 50 cooks, and maids; many of these will have had a say in its equipment, as for months past sample rooms have been on view at British Industries House where visitors have responded freely to the invitation to make suggestions in the books provided. Besides the living rooms the home will include a training school with lecture rooms, a model ward with dummy figures for testing probationers, a sun-roof for recreation, and what is promised to be the best dance floor in Westminster. Last but not least there will be ample storage room so that boxes and trunks will be eliminated from the bedrooms. Messrs. Adams, Holden, and Pearson are the architects. For the work of superintending the rebuilding, which will go on for at least four years before the whole of the hospital and its activities can be transferred to the new site, the present secretary of the hospital, Mr. Charles M. Power, has been relieved of his other duties.

CANCER OF GENITO-URINARY TRACT

THE treatment of malignant disease of the genito-urinary tract is dealt with in several papers in the *American Journal of Surgery*, and they form a symposium on the subject.[1] A. Hyman prefers the suprapubic to the cystoscopic approach when implanting radon seeds into bladder growths: his reasons are, first, that it is difficult to ascertain by cystoscopy the exact extent and character of the neoplasm; secondly, that the degree of infiltration of the bladder wall can be definitely determined only by a suprapubic approach; and thirdly, that accurate disposition of the radon seeds is best achieved by open operation. The most important detail in the actual insertion of the seeds is the use of many introducers, so that those first implanted may be left in situ until the others have been put in. This makes it possible to cover the whole field accurately, whereas if the needles are removed as soon as the seed is introduced one cannot be sure that radon is distributed over the whole area. Special precautions are taken to avoid implantation of detached fragments of growth; thus the bladder is washed out with 50 per cent. alcohol and the cystotomy wound is seared with an endotherm electrode before inserting the sutures. When the growths are widespread and the patient's general condition satisfactory enough to allow of a serious operation, total cystectomy with implantation of the ureters is recommended. Hyman prefers cutaneous ureterostomy to sigmoidal transplantation because it is a less severe operation and can be carried out at the same time as the cystectomy. Considering how appalling is the fate of the sufferer from extensive malignant disease of the bladder, his results must be considered extremely good. In 19 cases in which total cystectomy with cutaneous ureterostomy was performed there was an operation mortality of 21 per cent. Only 6 of the 15 survivors were operated on sufficiently long ago to provide significant evidence, but 5 of these were still alive after 5–8 years. Complementary to Hyman's paper is one in which B. S. Barringer gives notes of 36 patients with carcinoma of the bladder treated by cystoscopic application of radium who have been under observation for periods ranging from one to twenty years. Among them 27 were treated by cystoscopic application only while 5 had previously had suprapubic implantation, followed by recurrence; 2 were secondary to cervical carcinoma. The treatment carried no operative mortality, and in Barringer's opinion, provided the seeds are properly placed, there need be no danger of penetrating the bladder with a radon-bearing needle.

H. H. Young treats of the radical cure of cancer of the prostate by means of an extensive excision from the perineum. Since the technique of perineal prostatectomy is well known, the main interest lies in the results, and L. G. Lewis reports that of 50 patients who survived the operation 33 remained alive for five years or more, while 23 are still living without recurrence. The conclusion is drawn that all suspect prostates should be removed immediately, and if such good results can be got in the comparatively late stages of the disease, those to be expected with an early diagnosis should be still more gratifying. M. F. Campbell, writing on the surgical treatment of cancer of the penis, holds that when the growth is superficial—say, less than 2 cm. in diameter—and unassociated with metastases, a complete cure can be expected from irradiation alone. For larger growths, without involvement of the lymphatics, conservative amputation of the penis will be sufficient, but if the lymphatics are involved, a more extensive operation is needed. It should be remembered, however, that in at least half the cases in which the inguinal glands are felt to be enlarged, the enlargement is inflammatory and not due to the spread of malignant disease. F. Hinman, who describes the radical operation for teratoma of the testis, says that it was performed on 14 patients who gave no evidence of metastases, and 10 of them were still alive. At operation it was found that 7 of the 14 patients had involvement of the lymphatics, and 4 of these are alive fourteen years, four years, one year, and three months after operation.

Malignant disease of the kidney is reviewed by W. Walters and W. F. Braasch, and here again it is the result of operation that is chiefly of interest. Of 42 cases diagnosed as renal neoplasm at the Mayo Clinic in the past two years, 9 were regarded as inoperable, which suggests that about a quarter of growths of the kidney reach the surgeon too late. A more comprehensive study of post-operative results was made in 1933, when it was found that between the years 1901 and 1927, 256 renal growths had been treated by nephrectomy. Out of the 256 patients 110 lived five years or more after the operation; 22 lived ten years or more, 15 between fifteen and twenty years, and 5 more than twenty.

RELAPSING FEVER

THE importance of relapsing fever, both from an epidemiological and from an experimental point of view, is emphasised by Prof. Hindle's valuable digest of 168 recent publications on the subject.[1] The disease is one which has long disappeared from the British Isles, together with typhus, and since the late war it has steadily declined in Europe as a whole, though endemic foci still persist in Russia. On the other hand, an extensive and deadly epidemic of louse-borne relapsing fever has swept across equatorial Africa, starting from Upper Guinea about 1921. In the French Sudan and Nigeria the number of deaths caused during the first two years of this epidemic is estimated at 80,000 to 100,000; in north equatorial Africa, where it persisted until 1929, about 10 per cent. of the population died of the disease; and in Darfur one district alone had 10,000 dead out of 45,000. The infection was probably introduced from the Mediterranean region by Moroccan and Algerian soldiers, and the outbreak provides a striking example of the lethal potentialities of a disease which usually has a comparatively low mortality.

From time to time sporadic cases of what was evidently a tick-borne relapsing fever have been recorded from various parts of the southern United States, and recently it has been shown that in Texas *Ornithodorus turicata*, a tick found in caves and similar localities, is responsible for the transmission. As demonstrated by Nicolle and his colleagues in the case of North African relapsing fevers, wild rodents may harbour the infection, and as a general rule the spirochætes are maintained principally in this rodent population, though they are often capable of infecting other vertebrate hosts, including man. Study of the spread of relapsing fevers in many parts of the world shows that with few exceptions all varieties are transmitted either by lice, or by ticks belonging to the genus ornithodorus. The most notable exceptions are the occasional transmission of Spanish-African relapsing fever by a dog tick. *Rhipicephalus sanguineus*, and the possible rôle of *Dermacentor andersoni* in the spread of relapsing fever in British Columbia.. In addition, the bed-bug is found to be a more favourable host than was previously suspected, and in rare instances spirochætes may persist indefinitely in the hæmocele of bugs that have fed on infected blood; but epidemiological evidence does not support the view that they are of any importance in carrying the disease.

[1] Hindle, E.: Trop. Dis. Bull., May, 1935, p. 309

The study of chemotherapeutic agents against spirochætal infections has been greatly facilitated by the use of animals infected with various strains of relapsing fever. The method of administration is shown to be of importance, for irregular doses of neoarsphenamine (N.A.B.) may merely prolong the apyretic period without appreciably alleviating symptoms. Exposure to ultra-violet rays, or raising the body temperature, are both found to increase the efficacy of salvarsan compounds very considerably, especially in their effects on residual brain infections. Further, an interesting new method of studying chemotherapy is introduced by the chemical analysis of the mineral content of the spirochætes before and after treatment with organic arsenical or gold preparations. The results of these analyses suggest that the chemotherapeutic agent unites directly with the spirochætes, and that changes in this adsorbed substance bring about the formation of an actual poison, which acts on the parasite; but the cure is completed by the immune substances of the host.

ACCLIMATISATION TO GREAT ALTITUDES

THE preparations now in progress for a fifth attempt to climb Mount Everest in the summer of 1936 lend a topical interest to two recent contributions to the physiology of great altitudes. Dr. Argyll Campbell[1] brings forward evidence suggesting that the limit of acclimatisation may be reached at an unexpectedly low height. He has previously shown that (in the conditions of the experiment) rabbits and mice appear to have greater powers of resistance to low oxygen pressure for prolonged periods than has man—i.e., that they are more capable of maintaining normal appetite, health, vigour, metabolism, and body-weight. In the present paper he examines the behaviour of these animals in an atmosphere of 10 per cent. of oxygen, corresponding to an altitude of 20,000 feet, and shows that even after attaining good acclimatisation at a pressure of 12 per cent. they could not be brought to withstand the strain of life at a pressure of 10 per cent. of oxygen. Campbell quotes the observations made on Mount Everest in 1933 by Raymond Greene in support of his laboratory findings, but in applying his results in practice it must be remembered that, as he himself has pointed out, there are great individual variations in the resistance of animals to low oxygen pressure; and that, as Greene has observed, many factors besides mere oxygen shortage may enter into the consideration of human deterioration. The practical lesson of Campbell's work is this: that Everest teams should spend the maximum available time in acclimatisation below the North Col and the minimum possible time on the upper part of the mountain, and that the decision of the 1933 expedition to take oxygen in spite of much opposition to its use was a wise precaution.

A paper by Childs, Hamlin, and Yandell Henderson[2] raises the question of the possible usefulness of carbon dioxide to climbers at great altitudes. Insufficiency of oxygen often produces a period of overbreathing so excessive that carbon dioxide is washed out of the blood and a period of apnœa follows. The second period may be terminated naturally by the reinforcement of the mounting carbon dioxide by oxygen deficiency, or artificially by the inhalation of carbon dioxide from a cylinder. Experiments conducted on Pike's Peak by Childs and Hamlin seem to show that the breathing of 2–5 per cent. of carbon dioxide during exercise may have some slight effect in lessening the strain of climbing upon the heart and respiratory apparatus. The results of the experiments were not sufficiently definite, however, for important conclusions to be drawn. Moreover, Cheyne-Stokes respiration proves no serious handicap to carefully acclimatised mountaineers on the greater mountains. The experiment is worthy of repetition at greater altitudes, but is unlikely to be of assistance to the Everest expedition of 1936.

A MEETING of the subscribers to the Stanley Melville Memorial Fund will be held at the British Institute of Radiology, 32, Welbeck-street, London, W.1, on Thursday, Oct. 17th, at 4 P.M., to consider and decide the form the Memorial should take and the method of its administration. Friends of the late Stanley Melville are requested to send contributions before the date of the meeting to the General Secretary at the British Institute of Radiology.

Dr. Paul Dudley White, of Boston, U.S.A., will deliver the St. Cyres lecture of the National Hospital for Diseases of the Heart on Wednesday, July 10th, at 5 P.M., at the house of the Royal Society of Medicine. He will speak on congestion without myocardial failure, and members of the medical profession are invited to attend.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—Dr. T. A. Ross, formerly medical director of the Cassel Hospital for Functional Nervous Disorders, will deliver the Morison lectures in the hall of the College (9, Queen-street, Edinburgh) at 5 P.M. on June 24th, 26th, and 28th. He will speak on the teaching of the neuroses to medical students.

INDUSTRIAL HEALTH EDUCATION SOCIETY.—A meeting of the Industrial Health Education Society was held at 29, Portman-square, W., when Lord Luke presided, and the Duke of Kent spoke warmly to the meeting in support of the work undertaken. He found in particular that health talks to unemployed workers and unemployed boys' training centres had given valuable information, and that altogether the assistance of the medical profession in giving information to industrial workers on the diseases to which they are liable was most valuable. Lord Horder, president of the society, pointed out that while the grosser forms of occupational diseases which were much in evidence 20 years ago did not form the subject of these discourses, the whole standard of health among workers had already risen.

PROGNOSIS

A Series of Signed Articles contributed by invitation

LVII.—PROGNOSIS OF DIVERTICULITIS

DIVERTICULOSIS is the name given to the mere presence of diverticula in the colon, and it is only when inflammatory changes have supervened that the condition is termed diverticulitis. The diverticula are mostly situated in the sigmoid colon, and when inflammatory change occurs it does so almost invariably in this region, so that it is as a disease of the sigmoid colon that we shall discuss the condition here.

With the increase in the number of routine X ray examinations of the bowel, diverticula are discovered more and more frequently, and it is of importance in such cases to be able to foretell the likelihood or otherwise of the future development of inflammatory complications. When it is realised that some 10 per cent. of people over the age of 40 have diverticulosis of the colon, and that actual diverticulitis is comparatively rare, it becomes clear that the risk is not a great one; and even that risk can be minimised by dietary precautions and the avoidance both of constipation and of purges. H. K. Graham Hodgson (Brit. Med. Jour., 1931, i., 525) has pointed out that those cases in which the diverticula show in the X ray plate as having a translucent centre with an opaque periphery represent diverticula containing inspissated fæcal material round which the barium flows, and are the type most likely subsequently to become inflamed. Where diverticulosis of this type is found, it is essential to advise prophylactic measures in the form of a low residue diet, the avoidance of purgatives, and the exhibition of liquid paraffin both by the mouth and by the rectum, in order to avert the onset of diverticulitis.

TYPES OF DIVERTICULITIS

Cases of diverticulitis fall roughly into three categories distinguishable by their main symptoms as (1) the inflammatory, (2) the obstructive, and (3) the genito-urinary types, although it must be remembered that in all cases the lesion is of an inflammatory nature.

The *inflammatory* type is associated with a tumour in the left iliac fossa and with pyrexia, and its manifestations are similar to those of appendicitis only situated on the left side. Like appendicitis it is protean in type and extremely variable in gravity. In occasional cases the so-called "pistol-shot" perforation of a diverticulum, with resulting peritonitis may be the first manifestation, and in such a case—there being no time for the formation of protective adhesions—immediate operation is necessary, the prognosis depending directly on the time that has elapsed between the occurrence of the perforation and the institution of surgical measures to close it. The more usual condition, however, is the development of an elongated tender swelling in the left iliac fossa, associated with moderate pyrexia. The swelling varies greatly in size from the sausage-like tumour indicative of moderate pericolitis, to the large phlegmonous mass such as is not uncommonly found in relation to the appendix. In this type of diverticulitis medical treatment offers a good prognosis, but it must be persisted in until all tenderness and pyrexia have disappeared, and must be followed by careful prophylactic measures. If repeated attacks occur, which they frequently do, medical treatment is still the safest course, but if surgery is called for it must take the form of a colostomy, to be followed in suitable cases by excision when the acute condition has subsided. Some patients find themselves so free from symptoms after the first operation that they are willing to put up with the inconveniences of a permanent colostomy. Some cases, however, even when under treatment, develop to the formation of an abscess instead of undergoing retrogression, and in such the abscess must be drained. The important point is that on no account must radical surgery be attempted in the presence of acute inflammation, or fatal results are likely to follow.

The *obstructive* type of diverticulitis is frequently mistaken for carcinoma of the colon. Clinically it shows itself by gradually increasing constipation progressing to obstruction, associated with pain and tenderness in the left iliac fossa, pyrexia, and sometimes the presence of a tumour. The first essential in such a case is to relieve the obstruction by means of a colostomy, and if this is not unduly delayed it carries a minimal risk. At the same time it is usually possible to form an estimate of the feasibility or otherwise of the subsequent removal of the portion of bowel affected. It is not unknown in such cases for the diverticulitis to be mistaken for carcinoma at the operation, and many instances of alleged survival for many years after simple colostomy for supposed carcinoma are examples of this mistake. When resection appears feasible it is important to allow adequate time after the colostomy for subsidence of inflammation, and this can be greatly helped by repeated low pressure lavage of the affected bowel. There can be no doubt that for the actual excision an operation of the Paul-Mikulicz type is the safest. The area of bowel is mobilised with the utmost gentleness and is brought outside the abdomen. The afferent and efferent loops are sewn together for 3 in., and the diseased part of the bowel is cut off with a diathermy knife. The continuity of the bowel is restored later by gradual crushing of the spur between the afferent and efferent loops, and finally the small opening which is left, together with the original colostomy, can be closed. This operation because of its many stages is irksome to the patient, but it more than compensates in safety for its other drawbacks. The temptation of inexperience is to perform a primary excision and suture, but in diverticulitis such an operation carries a very considerable mortality and is only to be undertaken in the most unusual circumstances of extreme localisation of the disease and free mobility of the bowel on either side of it.

The *genito-urinary* type is the uncommon variety of diverticulitis associated with a vesico-colic fistula. Here the severity of the resultant cystitis as a rule overshadows the bowel trouble. The condition is commonly diagnosed as a malignant one, whereas in fact diverticulitis is a commoner cause of vesico-colic fistula than is carcinoma. The prognosis in such cases is always grave, and unless the cystitis is speedily relieved renal infection and death frequently follow. A colostomy with spur formation, so that none of the intestinal contents reach the fistula, is the first essential, and when that has been done, careful washing out of the lower bowel segment will diminish the severity of the cystitis. At a subsequent operation the bowel is separated from the bladder and the opening into this organ pared and inverted. The treatment of the colon will vary. Occasionally excision and union over a tube is possible, but usually after excision the upper end of the lower segment must be closed, and the patient will have to pay the price of a permanent colostomy for relief from the symptoms and dangers of his fistula.

RELATION TO CARCINOMA

Much discussion has centred round the question of the liability of diverticulitis to become malignant, and were the existence of such a risk established it would be inadvisable to persist with medical treatment. There is, however, little doubt that the patient with diverticulitis is no more liable to the development of carcinoma than is any other person, and fear of its occurrence need not in any way influence treatment. It is true that many cases are diagnosed as diverticulitis which are in fact carcinoma and vice versa. It is also clear that carcinoma, considering its frequency, must and does occasionally arise in a colon the subject of diverticulosis; but clinical experience, and the work of E. S. Judd and L. W. Pollock on specimens, both point to the conclusion that diverticulitis is in no sense a precursor of carcinoma.

SPECIAL ARTICLES

THE APPRAISEMENT OF HOOKWORM-KILLING DRUGS

BY CLAYTON LANE, M.D. Lond.
LIEUT.-COLONEL, INDIAN MEDICAL SERVICE (RETD.)

> "To ignore the past is to forfeit experience; to ignore the present is to make default to the future. . . . The new is not always true, nor is what is out of fashion always false."—(B. H. STREETER.)

To the query, "What drug best kills hookworms?" no reply can be given without first answering certain preliminary questions.

Should Deworming be Complete?

This question gets very different answers. In spite of emphatic disagreement, Garrison (1934)* maintained that cure meant complete deworming. Was he right? Or is there a worm-load proved to be negligible to host and to community? If so, how can it be determined? As to the host, Smillie and Augustine affirmed (December, 1925) that persons harbouring less than 100 necators need no treatment, but very shortly (January, 1926) they reduced this figure to 25. Neither conclusion emerges from their published facts (Lane, 1932), nor could the diagnostic means they used detect the lightly infected. No valid evidence has ever been produced of any such dividing line at any level.

For instance, Yenikomshian and Berberian (1932) retrieved 8 ancylostomes, with dramatic recovery of a gravely ill girl; and Ashford, Payne, and Payne (1933) retrieved 7 ancylostomes only from a markedly anæmic case, their accurate investigations yielding young worms 1·8 mm. long. If, as suggested, ancylostomes are twice as harmful as necators, grave illness could be caused by 14 necators, and if a dividing line exists between sick and carriers it must be much lower.

Pending the defining of such, the hosts' interest demands complete deworming.

As to the community, Molloy (1933) compared fæcal egg counts of 1455 persons before treatment, after one treatment with hexylresorcinol, and after two, and concluded that one treatment so lessened the hookworm load that it relieved most symptoms but did not eliminate all infective risk; accordingly a second seemed indicated, which might be by hexylresorcinol unless something better were preferred. The natural and apparently intended implication is that two treatments eliminate hygienic risk; but of the 618 persons who had two treatments with hexylresorcinol, over 500 remained infected; and taking a formed stool as averaging 100 g. this small group of presumably non-infective persons was actually passing at least 1,363,350,000 hookworm eggs *every day*. His paper was read at a joint session of the section of public health of the Southern Medical Society and the American Society of Tropical Medicine, and this unqualified advice passed without reported comment. To this hygienic position the policy of leaving a deliberate worm load has led. Such deliberate leaving in the individual of this or any other arbitrarily selected residual worm load is clearly opposed to the interests of both community and individual. Accordingly anthelminthic treatment should, as Garrison holds, aim at complete deworming. Whether it may rightly be pushed to this end is considered below.

Do Egg Counts Measure Worm Loads?

But while refusing to accept the conclusion just reached, some think that worm loads can be measured by fæcal egg counts. The evidence on the matter has been collected and arranged (Lane, 1932) with the conclusion that emphatically they cannot, either because corrections to the crude figures are necessary, or because they are actually being advised and used when they are not needed.

In the latter category lies consistence of stool. In the former lie age of worms, as Looss showed thirty years ago; their species, since *A. duodenale* perhaps lays eggs twice as quickly as *N. americanus*; interference by anthelminthics with oviposition, which caused Maplestone and Mukerji (1933) to reject egg counts in estimating the decrease in worm loads so produced in their hospital cases; weight of infection, as was first pointed out by Hill (1925)†; the presence of a second helminthic infection, which as Chandler (1932) showed may in the rat reduce to one-tenth the egg output of an existing one, peremptory disregard of a like happening in man being inadmissible; and diet, Foster and Cort (1932) reporting that in the dog it altered the egg count 1000 per cent., Looss having reported an opposite effect for man twenty years earlier.

Accumulating evidence does then but add strength to my conclusions (1932), "It is not possible from egg counts, however exactly made, to deduce with any approach to accuracy the number of worms which a person harbours." It was by inferring worm loads from egg counts that Smillie and Augustine based their conclusions above noted. Yet in discussing Molloy's paper (1933), Cort stated that egg counting was the only method usable under field conditions with groups of any size to test the reduction in worm burden produced by treatment. That is not so. Thus in commenting on Sweet's (1929) great work on 32,507 fæcal examinations in Ceylon, I have noted (1932) that with regard to hookworm infection the eight provinces with a single exception lay in the same order whether this was discovered by the tedious process of egg counting, or by the old and quicker one of noting the percentage of positives which one and the same diagnostic technique displayed. Which alternative is nearer reality? In fact, reduction of infectivity produced by massive treatment may be graded easily and rapidly by the growing number of negatives to a dependable diagnostic technique. Egg counts do not measure worm loads, and there are simpler, cheaper, and quicker ways of estimating hygienic risk.

---

* At the section of public health of the twenty-seventh annual meeting of the Southern Medical Association of the U.S.A.

† It is pleasant to make a correction here. Having overlooked Hill's conclusion to this effect, and having read Sarles subsequent demonstration (1929) of this fact in dogs, I turned naturally to Hill's fully documented paper for confirmation, and independently worked out, and reported, the point from his tables. It was only on re-reading the paper months later that I realised that he had already made it in his conclusions.

Do Egg Counts Measure Fæcal Egg Content?

Different egg-counting techniques differ sharply in the number of eggs which they disclose from the same fæcal base, and they cannot all be right.

Dilution techniques disintegrate fæces in some liquid. Water was used by Lutz and Leichtenstern in 1885 to determine worm-egg ratios, and led Looss; in 1897, directly to his great discovery of the skin route for hookworm infection. Stoll (1923) used decinormal sodium hydroxide solution, but has never offered any evidence that it is better than water; it dissolves albumin and chitinoid, of which the egg and its shell are composed, and it readily produces clumping of a fæcal suspension with uneven distribution of its constituents. Independent reports have not established the method's claim to accuracy. In my own hands it has proved the most erratic dilution egg counting technique tested. Ahmann and Bristol (1933) found that in their's it gave consistent counts only after a training period covering 50 slides and even then only when an average was struck of four or more counts from the same suspension, a precaution perhaps never yet adopted. A half-saturated solution of common salt (Control E., Lane, 1924) with a specific gravity evidently near that of hookworm eggs, has given me evener and higher average counts than any other dilution technique, and merits independent tests. By means of rising air bubbles the dilution-floatation technique of the Caldwells (1926) mixes fæces with a sugar and antiformin solution having a specific gravity of near 1200. The known forces at work seem predominantly lifting ones. I have been unable to get satisfactorily even results with it.

D.C.F.F.[‡] (Lane, 1924, 1932) has given me the evenest and highest average counts of any technique, but to obtain them instructions must be carried out. Particularly fæces must be completely disintegrated, and concentration must not be too great.

In improvised apparatus Hung (1926) exceeded the limit of effective concentration and obtained poor results. Stoll and Hausheer (1926), and Hausheer, Herrick, and Pearse (1926), altered the technique by deliberate rejection of the advised disintegrator (which comparative egg-counting tests have shown to be the best), by picking off floating debris after centrifuging (that is to say after eggs have become forcibly concentrated and entangled in them in numbers) and not before centrifuging as was advised (because counts have shown that nothing of the kind occurs then), and by rejection of instructions to scatter an uncountable herd of eggs and to use a square field for counting. They altered the technique in essentials, they obtained counts, poor and some of them typical of undisintegrated fæces, they transferred the discredit to the original technique, and they failed to repeat the experiments or to issue any modification of opinion after these serious changes had been pointed out; their conclusions have had wide acceptance. Soper too (1926) reported badly on D.C.F.F., but his success in adding to egg collection by stirring the sediment between spins is clear evidence of failure to produce complete disintegration.

No tests have disturbed the evidence that D.C.F.F., properly carried out, is at present the most accurate egg-counting technique. It has been controlled as follows:—

The ovum content of a fæcal sample has been determined by D.C.F.F., a known quantity has been cultured, and the number of infective larvæ recovered by extraction and by trapping counted. Trapping is essential, for many, sometimes all, larvæ may migrate from a culture before it is extracted (Lane, 1928, 1932) and unless the trap is so situated as to intercept them at once, they may dry up before reaching it, so that the total number retrieved may form no check on the number of eggs in the culture. Indeed in infection with the related œsophagostomum of sheep, Veglia (1928) relied entirely on emigration in determining whether or not the sheep host was clean; moreover cultures must be extracted between about seven and ten days of being set, since after that interval larval numbers are apt to lessen, evidently by death. Of 149 cultures kept at 28° C., and trapped, and extracted within that time, 5 showed more larvæ than were accounted for by the eggs delivered by D.C.F.F., the percentage increases in order of time being 17, 5, 4, 1 and 0·1. The first factor concerned in this steady diminution was skill in recognising, by appearance and movement under a 2 in. objective, free-living larvæ among swarms of hookworm larvæ; the second was the evolution of a drying technique which freed the culture earth from free-living nematodes, none being found in the last 280 cultures set, some of which had stood for weeks.

The reasonable conclusion from these controls is that D.C.F.F., properly used, is the most accurate egg-counting method, that egg counts made by it measure egg content, and that it constitutes a safe means of determining what diagnostic technique is the best.

What Diagnostic Technique is the Best?

Smears will unquestionably disclose every infection if sufficient area of sufficiently dilute fæcal suspension is sufficiently carefully examined, and twenty years ago smears were being used with that very aim, but were so time-consuming that concentrative techniques came into being. But these diagnostic qualitative techniques vary more in accuracy than do egg-counting quantitative ones. They can be accurately evaluated by egg counts only; and it is through D.C.F.F. that D.C.F. has been shown to be the best diagnostic technique at present available (Lane, 1932), and to be capable of disclosing a single normally ovipositing hookworm.

A normal female necator lays sufficient eggs daily to provide 28 to 45 of them in each gramme of fæces, a female *Ancylostoma duodenale* perhaps twice as many; D.C.F. uses 1 g. of fæces; in normal fæces it displays not less than 60 per cent. of them, so will disclose such a solitary female, a thing which no other technique can be depended on to do. Obviously one which uses 1/200 g. of fæces will miss such a necator infection some nine times out of ten. Further, Maplestone (1933) showed that short-lived infections with *A. braziliense* are readily acquired, D.C.F. displaying 3 to 4 eggs to a preparation, and expressed his belief that he would have missed these deliberately induced and closely watched-for infections had he used any other diagnostic technique. Eggs displayed by D.C.F. can with great ease be collected into a central herd, whose size or density may be used for grading egg numbers on a mass scale as satisfactorily as syphilitic infections are graded by the Wassermann reaction every day in laboratories all over the world. A combination of negative results with such an estimate of the size and density of the herd in positive cases will allow the effects of treatment to be *satisfactorily* checked, and since D.C.F. can be carried out at the rate of a quarter of a million examinations yearly by 4 men using a twelve-tube centrifuge, the matter is pre-eminently one of practical hygiene. When all these points have been realised, the waste of time and money entailed by egg counts, made as measures of worm loads, is unlikely to continue in public health practice.

[‡] D.C.F. or direct centrifugal floatation is a qualitative (yes or no) diagı [illegible] examines a single specimen obtained by [illegible] D.C.F.F. or direct centrifugal floatat [illegible] is a quantitative technique, aiming at [illegible] ıumber of eggs present by examining [illegible] rom 4 (plus 1) centrifugings.

Conclusions as to Methods of Appraisement

The value of egg counts as a measure of worm loads is illusory, and as a measure of fæcal egg content depends on the method used; evidence for complete deworming is the only stable criterion of drug efficiency; fæcal worm search to determine this is tedious, unpleasant, and not always evidence of worm loads; though smears, adequately and laboriously used, presumably effect this, D.C.F. is the only concentrative technique which will rapidly and certainly detect every normally ovipositing fertile female hookworm (every infection of present hygienic risk), and it will do so at the rate of a quarter of a million examinations a year with one team of four men and one centrifuge; hygienic risk caused by infected persons can be graded rapidly, usefully, and empirically by estimating the size and density of the herd of eggs which that technique displays; and the lessening of hygienic risk produced by mass treatment is the proper and adequate measure of the success of such treatment.

What Drug Best Kills Hookworms?

When these conclusions are applied to hookworm-killing drugs, satisfying appraisement is found to be impossible, seeing that observations on different drugs have been made by methods too various to be comparable, and that for twenty years test by deworming has been neglected.

The problem has two parts—efficiency and safety. With no exception at all *safety must come first*, for the infection is in man and it rarely kills directly. Moreover, success and safety achieved in an institution need not be repeated among millions of infected persons in the field, nor can they be looked for unless the drug has a definite composition.

Oil of chenopodium has no such stability. When in greatest vogue its active principle, ascaridole, was still undetermined. This is deadly to man and worm, the respective lethal doses lie near one another, and its reported percentage in the oil has varied from 33 to 98. Further, the size of drops varies with different droppers, and there has been catastrophic confusion between 45 drops on the International Dropper (or 1·2 c.cm.) and 45 minims (or 3 c.cm.). Numerous deaths have followed the latter, apparently none the former, which at a percentage of 66 implies 0·8 c.cm. of ascaridole. To give the oil without knowledge of its ascaridole content is indefensible—but customary. Many tens of thousands of doses have been reported, in few has its ascaridole content been known, and in none of these has deworming been the method of measurement. In other words, I find no acceptable published evidence of its efficiency against hookworms.

The other drugs much used have definite chemical structures.

THYMOL

Thymol was in greatest use when prolonged examinations aimed at, and must often have succeeded in disclosing, deworming. For successful use it must be particulated. Thymol crystals readily set into a solid mass, so that when packed into a digestible capsule its shape may still be recognised in the now bare lump of wasted thymol passed in the fæces. Proper dispensing quite alters matters. B. E. Washburn and G. C. Payne showed in Trinidad nearly twenty years ago that when the drug was finely ground and then intimately mixed with at least an equal quantity of sugar of milk, deworming after two treatments increased from 12·6 per cent. to 49·1 per cent. Comparable results were reported from British Guiana and Ceylon. In all these cases post-treatment examination was so minute as to have been nearly or really accurate.

Giles (1890) held that particulation was best obtained by pouring an alcoholic solution into, say, eight times its volume of water and shaking.

The microscope then shows tiny globules of thymol-containing fluid moving about in the water. Their further behaviour varies. In a series of the writer's experiments at room temperature using a 50 per cent. solution in rectified spirit diluted and emulsified in this way, crystals began to form in two and a half to seven minutes on the surface of portions poured into open flat dishes, and in 30 minutes in those kept in closed flasks, the thymol-containing spirit having first collected into considerable globules on the surface. If Giles's observation on anthelminthic power was made on persons who received the drug as an emulsion, this presumably behaved in the stomach as in a closed flask, and absorption began from an alcoholic solution. But after forming, surface crystals are apt to grow rapidly into plates, far larger than the crystals of the drug as dispensed. Yet these crystals need not be allowed to form, for if initial shaking is so vigorous that the alcohol is rapidly diffused in the water, thymol forthwith precipitates out in fine, loose flocculi which do not afterwards aggregate into plates. The swallowing of the drug in a state of microscopic subdivision is, then, no guarantee that it remains so in the alimentary canal.

Several physical conditions may result when thymol solution is shaken up in water, and they are capable of influencing in several directions its absorption; for contrary to much teaching absorption should seemingly be one's aim. Thus Caius and Mhaskar (1919) showed that particulated thymol is completely absorbed, none being passed in fæces even when, with the drug, was given enough Epsom salts to produce purgation within 45 minutes. Two conclusions follow. Firstly, the fear that the taking of alcohol will, by its ready solvent action, produce too great absorption can hardly be correct. Secondly, since most of the absorbed thymol was not accounted for by the amount of its known derivatives in the urine, it must have been changed in the body into something else; quinine and emetine are so changed into active parasiticidal substances. Presumably (Lane, 1932) the actual vermicide after thymol is something else than thymol and is absorbed by hookworms from the blood, so that complete absorption should seemingly be our aim with thymol. Giles, a good observer, offered no figures in support of his view, and only extensive comparative tests can determine whether he was right, or alternatively to what degree of fineness crystals should be ground to give best results. On available evidence it may be concluded that two courses, each of 60 grains of "finely particulated" thymol, will effect deworming in about 50 per cent. of adults.

Moreover, such deworming is safe in those not already moribund or nearly so. I have reported (1932) all the deaths after thymol which I could collect. With but a single exception no two autopsies have shown the same lesions, the exception being two brothers who disappeared into the woods together for some two hours after a thymol administration and died of acute gastro-enteritis. It is not in accord with medical experience and usage to attribute to a drug lesions which have in all cases but one pair been different, and that pair having peculiar circumstances. Howard (1919) pointed out how persistently it was stated that sixty-grain adult doses of thymol were dangerous, but that there had actually been given over a million such doses in the United States with no death, and that few drugs could stand so severe a test. Last year I received a letter from the late Bailey K. Ashford in which he refers to 1,600,000 doses given by him in Porto Rico without a death, and towards the end of last year I had another from a young and distinguished lay American helminthologist reiterating the legendary risks from thymol, but when details in substantiation were urgently requested, he let the matter drop. I believe there is no evidence. If it can be found it should, in the interest of human life, at once be displayed. Actually thymol is as safe as it is because, like alcohol, it is apt to produce early symptoms of intoxication, and the intoxicating dose is far removed from that which kills. The figures I have quoted show how much justification there is for this strangely persistent legend, and I think that few who repeat it have any adequate experience of the drug's use. The figures were obtained by disinterested persons whose experience of thymol is unrivalled; my own 60,000 administrations without anxiety are relatively unimportant, for as Ashford, Payne, and Payne write, "We must remember Maurice Hall's wise observation that the limitations of an anthelminthic can hardly be known save after a hundred thousand well-observed administrations."

Beta naphthol.—The minimum lethal dose is 20 grains (1·3 g.) (Milne, 1933), and lower doses are not efficient.

CARBON TETRACHLORIDE

The following few instances have been found in which evidence of deworming has been used to measure the efficacy of carbon tetrachloride.

Field (1924) gave 4 c.cm. and, checking results by six smears and three examinations by a floatation technique, obtained a cure percentage of 77. Maplestone and Mukerji (1929) gave 3 c.cm. to sixty hospital patients, and using D.C.F. obtained a cure percentage of 48, while the same dose combined with 1 c.cm. of oil of chenopodium of unstated ascaridole content gave 46·4 per cent. of cures in 69 cases. The minimum lethal dose is 1·5 c.cm.

As to safety there are two sets of reports.

On the one side is Lambert's assured call (1933). "I report more than 100,000 consecutive treatments with carbon tetrachloride without a death"; but he does not there mention that earlier he had had 42,500 cases without a death, and then 3 deaths in the next 8000—deaths which he attributed to impurities, although the lesions found were reported by Darling (Lambert, 1923) as "unquestionably caused by carbon tetrachloride." Again, Tomb and Helmy (1933) report that in 1,600,000 doses they had 19 deaths, 6 being immediate in twenty minutes to six hours, and 13 delayed for two or three days with typical lesions. In the same number of doses reported for thymol by Ashford there were no deaths. What advantage justified the use of a drug which caused those 19 deaths? None is offered. Khalil (in Hassan and Salah, 1935) reports that 7 to 8 cases of "carbon tetrachloride poisoning" are reported yearly by the Parquet in Egypt. On the other side are reported high mortality-rates (*v.* Lane, 1932), of which only three examples need be repeated: Ziya Bey (Hussameddin, 1931) 1 death in 1200 administrations with an adult dose of 2 c.cm., Nag (1929) 3 deaths in 289 children, the dose being 2 c.cm. for a child of eleven, and Straub (1925) 2 deaths in 400 Chinese and Klings, the men receiving 2·5 and 3 c.cm., respectively.

The drug holds a unique position. It causes definite lesions. Its minimum lethal dose accompanied by typical lesions is 1·5 c.cm. (Bais, 1924), and the dose given in the British Pharmacopœia is up to 4 mils.

Tomb and Helmy (1933) hold that since after large doses most of the drug is passed unchanged in the fæces, large are safer than small ones; an unacceptable conclusion, for the quantity absorbed and not that remaining unabsorbed must govern safety, and Robbins (1929) showed that the larger the dose the greater the absorption, and therefore surely the greater likelihood of that hepatic and renal damage that kills. Moreover, hepatic damage is greatest round the hepatic vein, regeneration taking place from cells surviving beside the portal vein; but in autopsies recorded by Ashford and King (1907) on established deaths from ankylostomiasis itself (no carbon tetrachloride having been given) fatty degeneration was always present, and was most marked about the portal vein. Hookworm infection itself then, as they report, injures just those areas from which hepatic regeneration must start if life is not to be lost from carbon tetrachloride poisoning. Again, a factor making for death from the drug is excess of guanidine in the blood, the antagonism between guanidine and calcium has been repeatedly demonstrated, while Ashford (1933) notes from long experimental work with Hernandez that nutritional unbalance itself produces calcium deficiency, and that it is precisely among such persons that antihookworm work has usually to be undertaken. The dangers of comcomitant ascaris infection are real.

Further, Soper, of the Rockefeller Foundation, reports (1935) on the anxiety felt since 1932 regarding recrudescence of yellow fever in South America, where over 50,000 liver specimens were examined. In a large series collected in Ecuador pathologists disagreed on the significance of the lesions, immunity tests in children were negative, no cases occurred in the cities, and the clinical histories of the dead were inconclusive. But these last had one common factor—all but one of them had received anthelminthic treatment before dying. On the numbers of these deaths, the drug or drugs used and their dosage the paper is unfortunately silent (doubtless full details of these are being made public); but J. W. Lindsay, of Paraguay, tells me that the ordinary mass treatment of hookworm infection in that country (carbon tetrachloride or oil of chenopodium, or both, in standard doses according to age, by native orderlies not always under professional control) has in some districts, among the underfed, calcium deficient population, been followed in children by deaths, and in adolescents and adults by ruined health with swollen liver and yellow-ochre jaundice.

The position is this. The use of carbon tetrachloride is strongly pressed on backward races in doses considerably greater than the minimum lethal dose; its deadliness depends on an individual variability in the patient; some of the factors in this variability are known; and no attempt is being reported in its massive use to determine whether such as are known are all absent in the treated, and often none to ascertain whether these are infected or not. Is not this rightly termed "herd treatment"? Is herd treatment justifiable for man?

TETRACHLORETHYLENE

The following instances have been found in which tetrachlorethylene has been tested by evidence for deworming:—

In doses of 3 c.cm. it was given by Maplestone and Mukerji (1929) to 40 patients, with a cure-rate to D.C.F. of 15 per cent.; and at the same time they reported a like cure-rate of 26·2 per cent. in 42 cases when 1 c.cm. of oil of chenopodium of unstated ascaridole content was added to the same dose of tetrachlorethylene. They repeated the latter test (1933) using 4 c.cm. of tetrachlorethylene and 1 c.cm. of oil of chenopodium of unstated ascaridole content, and obtained by D.C.F. in 50 cases 62 per cent. of cures in one treatment, and 74 per cent. in two. What caused the marked difference in the results of their two experiments is not clear; several factors varied, but that the better results are those which may be expected in future cannot be accepted without further investigation.

These writers advise that this mixture should be shaken into an emulsion with 2 oz. of saturated solution of magnesium sulphate, so that it may reach all worms in the intestine in this state of subdivision, with efficiency thereby increased. This advice can hardly be sound, for as to the chenopodium Darling, Barber, and Hacker (1920) reported better results when it was given as an oil than an emulsion, and as to tetrachlorethylene, my own experience is that, within ten seconds of ceasing to shake up 4 c.cm. of tetrachlorethylene in 2 oz. of magnesium sulphate solution, the former has again begun to collect at the bottom of the flask, and that nearly all of it has so separated out in one minute. The chance of its reaching all the worms in the small intestine in a state of fine subdivision does not seem to be increased by the manipulation.

The dosage employed by Garrison (v. supra) for children of ten was 9 c.cm. in all, namely, 3 c.cm. weekly given on one morning in hourly doses of 1 c.cm. and followed by a purge, the child being kept in bed on the day of treatment. As to cure, a brine-floatation method showed 7 per cent. positive four months later. Garin, Rousset, and Gonthier (1933) gave 5 g. doses daily on three consecutive days, and obtained to a modified and unevaluated Telemann technique a cure-rate of 82·5 per cent. They compared it with thymol given in the same way in 3 g. doses, and which they held to be particulated by being finely ground and mixed with about a hundredth of the amount of magnesium carbonate necessary to produce particulation; its cure-rate to the same technique was 47 per cent. Their conclusions are not of comparative value, but are cited to emphasise how essential is attention to detail before fair comparisons can be made.

No death has been reported from tetrachlorethylene, though Kendrick (1929) had grave anxiety in one of 500 administrations after a dose of 3 c.cm. in a man weighing 100 lb. In a paper silent as to its anthelminthic effect, Lambert (1933) reports 46,000 treatments in the South Pacific without a death. Maplestone and Mukerji urge that, as was pointed out above for thymol, the symptoms may be compared with those of drunkenness. The drug merits massive, controlled, field investigations, but present claims to its pre-eminence are premature.

HEXYLRESORCINOL

No attempt has been traced at evaluation of hexylresorcinol through deworming. Molloy's cure-rate was clearly much less than the 19·4 per cent. claimed after two treatments as judged by Stoll's technique; for in 12 post-treatment cases this method disclosed to Maplestone and Mukerji (1929) four positives while D.C.F. displayed eleven. The drug has hitherto caused no deaths. Relative success depends on starvation, rigorous to a degree required for no other anthelminthic.

The many complaints of oral erosion when children bit the capsule induced, it is reported, its withdrawal by the makers from unrestricted purchase in the United States. In cats (Maplestone and Chopra, 1934) erosion of the gastric mucosa is histologically negligible in doses of 1 grain per kilogramme; but local action must depend on local concentration, and when this was produced by putting a big dose into a cat's small stomach there followed necrosis of the mucosa to half its depth. Similarly in a man with strongyloides infection it caused marked gastric irritation (without lessening of larval numbers passed in the fæces); accordingly these writers urge the need for careful selection of cases.

Encapsulation of the drug shifts to the invisible stomach the ugly necrosis it causes, but æsthetic gain need be no more than a decent shrouding of pathological damage. Hope of its usefulness on a mass scale is slight.

A COMPARATIVE TEST

Failing tests by deworming one must fall back on comparative tests in which control of single factors seems to have been attained. Only one such series has been discovered comprising three of the drugs. Caius and Mhaskar (1919, 1920, 1923), using the Schüffner-Vervoort method of trial and test drug with 60 grains of particulated thymol for the test treatment, got the following results with *A. duodenale* and *N. americanus*, respectively; particulated thymol 4 g. in one dose, 96·1 and 99·6; ascaridole 1 c.cm., 60·9 and 83·4; carbon tetrachloride, 1 c.cm., 11·5 and 90·8, 3 c.cm., 76·4 and 96·3.

General Conclusions

In my first section the conclusion was reached that deworming should be our clinical and hygienic aim, to which it is objected that to push a potentially lethal drug in an effort to attain this object, in an infection which itself rarely kills directly, is morally unjustifiable. But where is the evidence that thymol used with individual care is potentially lethal? Methods of drug appraisement have been summarised, with the conclusion that, from this point of view also, evidence for deworming should be their basis. Finally, the drugs have been so considered, and I have laid out all the evidence I have been able to find which fulfils the necessary conditions. It seems to leave thymol in the first place, especially when safety and efficiency are both considered, it being again stated emphatically that *safety must have the first place.*

It has been said that I have appeared as advocate in the case of thymol *v.* carbon tetrachloride, and have "perhaps unconsciously" weighted the evidence in favour of my client. Where human knowledge and human life are at stake, suggestions of such bias should be substantiated, but nothing of the kind has been attempted by that writer in the years that have since passed. Again, this conclusion of mine, based on published evidence (that properly administered thymol remains preferable to all the newer anthelminthics), has been designated as reactionary and prejudiced; but in this connexion it seems worthy of note that other conclusions of mine (dealing with the point reached by existing evidence on the mechanical basis of microfilarial periodicity) have been described as revolutionary. A sane person whose mind runs equally readily to revolution and reaction in kindred subjects must be somewhat of an oddity. Perhaps after all the appropriate adjective in both cases is rational.

The bulk of what has been offered as evidence for appraising hookworm-killing drugs has been reached in non-comparable ways. What is good I have attempted to sum up fairly. These conclusions are before a jury of medical men in private and public health practice, men fully competent to decide whether the evidence offered is or is not good. But in face of its meagreness the matter should not rest there. There is so much of human life and human happiness at stake that the immediate future should see a serious effort made, by unprejudiced and independent qualified medical workers, to add to acceptable and controlled evidence regarding the real value and safety of hookworm-killing drugs. If this paper does not initiate the collection of a sufficiency of such evidence by such men, it will have failed in its most important aim.

ROYAL INSTITUTE OF PUBLIC HEALTH AND INSTITUTE OF HYGIENE

CONGRESS IN HARROGATE

A CONGRESS was held in Harrogate by the united Institutes commencing on Tuesday, June 4th, and concluding on Whitsun Sunday, June 9th. The congress met under the presidency of Lord Harewood, and its work was carried on under five sections: (1) State Medicine and Hygiene; (2) Women and Children and the Public Health; (3) Tuberculosis; (4) Rheumatism and Allied Diseases; and (5) Hydrology, Climatology, and Meteorology. The ground covered in the communications was extensive. These will be published, as far as possible in extenso, in various issues of the *Journal of State Medicine.* Certain of the debates which roused the principal interest in the different sections are here noted.

Dr. Johnstone Jervis, M.O.H. for Leeds, pointed to bad housing as still remaining the chief cause of tuberculosis. Dr. W. S. Gilmour, medical superintendent of the City of Leeds Sanatorium, said that tuberculosis accounted for about 50 per cent. of all the deaths in young women, and Dr. N. Tattersall pointed to the long hours of work in factories imposed upon girls who had only just left school. Compared with the strains of industrial life, he held the cocktail habit and other accompaniments of social life to count for little. Sir Pendrill Varrier-Jones said that despite all efforts tuberculosis succeeded in killing four or five times as many people as the motor-car. In his experience tuberculous people could do excellent work if given a chance to make good by employment. He asked whether it was not better to subsidise their industry than their enforced idleness when driven into the ranks of the unemployed.

Dr. L. P. Lockhart, member of the Industrial Health Research Board, introduced an interesting debate on the position of the sexes in modern society. The welfare of women, he thought, would never be properly advanced until their supposed lack of mechanical ability and their supposed instinct for cooking and textile work were found to be inaccurate generalisations. Women, he said, need freedom, not to do as they like, but to assume their full share of responsibilities in industrial and economic life. The challenge was taken up by several speakers who pointed out, among other things, that too many women were found in offices and factories who would be far more efficient in discharging household tasks; that if a married woman entered the labour market she could not do her work at home properly; that it was degrading to see women engaged in industries once the stronghold of men; that properly cooked food from a communal kitchen was better than ill-cooked food from the domestic oven; and that when women entered industry they were used as a lever to pull down men's wages.

A debate on the need for the greater standardisation of food products produced some straight talking. Dr. King Brown, instancing sausages as a valuable article of diet whose contents varied so enormously that standardisation was required, urged that the public should be protected from misleading advertisements. In illustration of this Dr. H. M. Holt said that the public ate under the heading of confectionery things sold as cream buns which had no cream. Dr. Jervis held that food standardisation, if it raised the prices by safeguarding the value of the product bought, would save much expense later on in medical and hospital treatment. Dr. G. E. Oates, M.O.H. Paddington, criticised the working of the Milk Marketing Board, and Major D. S. Rabagliati urged that the producer should be encouraged to go in for tubercle-free milk.

Dr. Doris Odlum spoke of the necessity that teachers should be better fitted for their work by taking a course of psychology, believing that the average mother would accept guidance in bringing up her children if the educational system provided teachers who had had some appropriate training. She criticised also the children's courts, the presiding magistrates not having proper psychological equipment.

SPA TREATMENT

Dr. Alfred Cox, general secretary of the British Health Resorts Association, opened a discussion on spa treatment for industrial workers, pointing out that in Great Britain no use was made of the opportunities for the relief of disease provided by spas, while in France and Germany no place could be recognised as a spa unless it was prepared to treat a certain number of cases free and a large number at reduced rates. Many industrial workers, he said, were suffering from diseases which spas could best deal with, but the advantages of the British spa are too often not available for them.

In this section of the congress Dr. Howard Humphris read a paper in which he suggested that the known beneficial qualities of spa treatment are not in this country sufficiently related to the radium emanation contained in the waters. He held that in radium emanation taken at the source of origin the main secret of spa benefits could be found. "The secret of the spas," he said, "is identical to radium emanation," and he pointed to the excellent results of mild radium therapy, so that it was unfortunate that British spas should labour under the disadvantage

of not being able to supply mild radium therapy. The task of installing it in every spa could be accomplished with very little difficulty and expense by means of a specially constructed apparatus, the emanator, which he described.

An attractive handbook was published on the occasion of the congress, setting out the claims of Harrogate both as a medical centre and as a place of recreative sojourn. The compilers have realised that while the medicinal springs must be the main reason which attracts the public to the spa, the invalids are usually accompanied by relatives and friends, while both those who are sick and those who are whole require diversion. In this handbook Mr. S. P. B. Mais points out that Harrogate is the central point between London and Edinburgh, between John o' Groats and Land's End, and between the east and west coasts, and is a stepping-off place for those who wish to see England at its richest, historically, architecturally, and pictorially. Harrogate has received more than one description in these columns, and its scenic magnificence and efforts to provide amusement as well as "cures" are well known to most medical men. We may refer our readers to the account of a conference held there under the auspices of the British Health Resorts Association last year (THE LANCET, May 19th, 1934), as showing what advantages the spa can offer to the suitable patient.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY

ANNUAL GENERAL MEETING

THE annual general meeting of the society was held at Victory House, Leicester-square, London, W.C., on Wednesday, June 12th, 1935. The chair was taken during the first part of the proceedings by Dr. G. F. STEBBING, chairman of council, who said, in moving that the annual report, statement of accounts, and balance sheet be received and adopted, that the year had seen a large increase in the amount of work of the society, the applications from members for advice and assistance having risen in number from something like 1200 the year before to 1460 during the year under review. He added "there has been a considerable increase in the membership of the society; we have elected 984 new members during 1934. It is interesting to notice that on the average we have had an application for assistance from every ten of our members—in other words, 10 per cent. of our members have had occasion to turn to us during the year. The society has ample funds at its disposal, and has never hesitated to use them when the members' interests required it, and this year an amount actually in excess of the subscription revenue has been spent on behalf of the members." Dr. Stebbing then referred to the extremely varied nature of the work undertaken for the members, alluding specially to questions connected with National Health Insurance, as well as to the variety of troubles and accidents which might happen to the practitioner in the course of his duties, some of which might only incidentally relate to practice but nevertheless must greatly affect the welfare of the doctor. He pointed out that apart from legal defence and advice the society was able to help members on many matters which might seem scarcely to come within the strict scope of their business but where none the less guidance might benefit a member. He recalled the memories of Sir John Rose Bradford and Sir Thomas Parkinson in a few words, and closed by alluding to the necessity of an extraordinary general meeting to approve certain alterations in the Memorandum of Association.

Dr. R. L. GUTHRIE, the treasurer, pointed out that the balance sheet and accounts contained in the report required little explanation. He reminded the audience that the year 1934 could hardly be as prosperous pecuniarily speaking as its predecessor because a number of expenses and unsettled cases were outstanding at the end of 1933, so that but for a profit made by the sale of certain short-dated securities there would have been a small loss in 1934. Disclaiming the gift of prophecy, he said that the prospects this year looked better as the society had not so many expensive cases in hand. The capital position he pointed out was sound; all the investments were gilt-edged and appreciation of capital value had further increased. The policy of the society, however, had always been to keep the assets liquid and available for the benefit of members rather than to hoard up reserves, and in the year under review the analysis of expenditure showed that 16*s.* 3*d.* of a pound subscribed by members had been spent in their legal defence.

Sir CHARLES GORDON-WATSON then proposed that Sir Cuthbert Wallace should be elected president of the society in the place of the late Sir John Rose Bradford. The resolution, being seconded by Mr. Sidney Spokes, was carried unanimously with applause, and Sir Cuthbert took charge of the meeting.

The election of the vice-presidents followed, when Dr. C. O. HAWTHORNE spoke eloquently of the loss which the society had sustained by the death of its late president who had spent so much time and employed so much experience for the benefit of the society, while he added words of personal welcome to Sir Charles Gordon-Watson.

The re-election of Dr. R. L. Guthrie as treasurer and Dr. C. M. Fegen as secretary followed, and the meeting closed with votes of thanks to the solicitors, Messrs. Le Brasseur and Oakley, the auditors, Messrs. Duncan, Allwork and Co., and to the staff.

EXTRAORDINARY GENERAL MEETING

An extraordinary general meeting was then held when certain resolutions were submitted as special resolutions. The chair was taken by Dr. Stebbing, who said: "The first resolution concerns a proposed alteration in the provisions of the Memorandum of Association. This alteration has become necessary because of the situation that has arisen owing to the passing of the Law Reform (Miscellaneous Provisions) Act, 1934. Under that Act it has now become possible for actions to be commenced against the estate of deceased persons in regard to some act or fault during their lifetime. It has been recognised that this may have a detrimental effect on the estate of a deceased member, as owing to membership ceasing with death, the society would not have been in a position to defend his reputation. This alteration is being made to meet that situation, so that the Association may be in a position to protect a member's character and reputation after his death.

"As we have to make this amendment, we have taken advantage of the occasion to make a further small alteration so that we may further the coöperation which has existed between this society and the Medical Defence Union. It sometimes happens that in respect of deeds of partnership or other circumstances it is desirable for a member to change from one society to another. There was a period after such change during which a member was unprotected. The purpose of the alteration of the Articles is to protect the member fully. I propose the following resolutions as special resolutions:—

"1. That the provisions of the Memorandum of Association of the society with respect to the society's objects be altered as follows: By inserting between para. (c) and para. (D) of clause 3 of the Memorandum of Association of the society the following para. (cc), namely: '(cc). To grant to the personal representatives of any deceased member of the society any of the privileges which such member would have been entitled to as a member if he were still living.'

"2. That the Articles of Association of the society be altered in manner following, that is to say: (*a*) The following words, viz.: 'or his personal representatives' shall be inserted after the word 'member' where such word occurs in Article 16 of the Articles of Association of the society excepting where the word 'member' occurs in proviso (A) of such Article. (*b*) The following words, viz.: '*unless he was a member, at the time of the cause of action arising, of another Association with objects similar to those of the society*' shall be added to proviso (A) of such Article 16."

The resolutions proposed from the chair were put to the meeting and declared to be carried unanimously and the business of the meeting then concluded.

MEDICINE AND THE LAW

Statutory Restrictions on Professional Advertising in America

IN many of the United States of America the practice of dental surgery is regulated directly by the legislature instead of standards of professional conduct being left, as in this country, to be defined and enforced by an autonomous council containing representatives of the practitioners. An interesting decision has lately been given by the Supreme Court of the United States in connexion with a law passed by the State of Oregon in 1933. The State had enacted that a licence to practise dentistry might be revoked if the licence-holder was guilty of various improprieties which in Britain would be breaches of professional etiquette recognised as such by rulings of the General Medical Council and possibly emphasised by warning notice. The improprieties were thus set forth in the Oregon statute:—

"Advertising professional superiority or the performance of professional services in a superior manner: advertising prices for professional service: advertising by means of large display, glaring light signs, or containing as a part thereof the representation of a tooth, teeth, bridge work or any portion of the human head: employing or making use of advertising solicitors or free publicity press agents: or advertising any dental work or free examination: or advertising to guarantee any dental service or to perform any dental operation painlessly."

It is understood that in the past three years many other States of America have enacted similar laws so that gradually a uniform professional code is being extended throughout the whole country. The subject of professional conduct is one which is within the legislative competence of the several States; the Federal Legislature does not deal with it. But, owing to the rigid written constitution of America, it is often possible to argue that a legislature (either a State legislature or the Federal Legislature itself) has exceeded its functions by overstepping the prescribed boundaries.

A recent illustration, annotated in the *J.A.M.A.*, June 1st, was the decision of the Supreme Court of the United States which held certain enactments invalid on which President Roosevelt relied for his "new deal." A dentist in Oregon, having apparently offended against the Oregon statute, invited the courts to rule that the statute was unconstitutional inasmuch as it denied due process of law and equal protection under the law and impaired the obligation of contracts. Such an argument against an Act of Parliament in England would be impossible; we have an elastic constitution with nothing rigid except in the inter-Imperial field where nowadays the Statute of Westminster applies. Our Parliament is bound by no written limits but can pass any laws it likes. The Oregon dentist, alleging that the statutory restrictions on advertising offended something fundamental in the American constitution, failed to make good his contention in the courts of his State and appealed to the Supreme Court of the United States. Here he met with a further rebuff. The Supreme Court declared that the State legislature was fully authorised to check the harmful effects of professional malpractices. It was not a matter of traders in commodities, but of public health and of a profession demanding standards of conduct different from those which are traditional in the competition of the market place.

"The community is concerned with the maintenance of professional standards which will insure not only competency in individual practitioners but protection against those who would prey upon a public peculiarly susceptible to imposition through alluring promises of physical relief; and the community is concerned in providing safeguards not only against deception but against practices which would tend to demoralise the profession by forcing its members into an unseemly rivalry which would enlarge the opportunities of the least scrupulous. What is generally called the 'ethics' of the profession is but the consensus of expert opinion as to the necessity of such standards."

The position has seldom been stated in more weighty or more dignified language.

One point had been stressed by the appellant. He claimed that his advertisement of "professional superiority" was nothing but the truth, and he asserted that the law could not interfere where no unwarranted or misleading assertions had been made. The Supreme Court gave no countenance to this argument. The legislature, it observed, when framing a policy, was not bound to provide for assessment of the relative proficiency of individual practitioners. It was entitled to consider the general effects of the practices which it described; if those effects were injurious in facilitating unwarranted and misleading claims, the State was entitled to counteract them by a general rule even though in particular instances there might be no actual deception. Thus the standards of professional conduct in the United States and in this country are reaching the same salutary level though by different methods of approach. In the one case the legislature intervenes; in the other it delegates control to an ad hoc body whose actions and decisions public opinion is prepared to accept as authoritative.

Hospitals and the Companies Act

A public notice in the press shows that the Queen's Hospital for Children is applying to the Board of Trade (under Section 18 of the Companies Act) for a licence to be registered as a limited company without the addition of the word "limited" to its name. This is a convenient procedure where an association is to be formed or maintained "for promoting commerce, art, science, religion, charity, or any other useful object," and where the profits or income (if any) will be devoted to promoting the object and not to the payment of a dividend to the members. Such an association, if thus registered, enjoys substantially all the privileges of limited companies. It gains in stability and permanence, for it becomes a body corporate with perpetual succession just as if it had been incorporated by Act of Parliament or by Royal Charter. It can hold property in its own name without the intervention of trustees; it can make contracts and can take and defend legal proceedings in its own name. It can conduct its affairs more efficiently and its officers and members are freed from personal liability.

When in 1867 Parliament first provided this facility for constituting a company under the Companies Act while dispensing with the word "Limited," advantage was taken of it by local chambers of commerce, law societies, and trade protection societies. Gradually the scope was widened, and in the next 15 years the companies thus registered included such various examples as the College of Organists, the Institution of Mechanical Engineers, the Cheltenham Ladies' College, the Palestine Exploration Fund, Newnham College, and the British Dental Association. Where the registered company is absorbing some existing association, the property is transferred to the new entity and, unless there is legal difficulty over some question of trusts, the transition from the old organisation to the new is easy. The new company can declare its objects in wide terms. Thus a hospital can obtain powers not only to maintain its charitable services for the poor, but also to provide accommodation for payment where patients can afford to pay. Naturally, like ordinary companies under the Companies Act, it will state its purposes comprehensively because the law will confine the body's future activities within the limits so defined and anything outside those boundaries will be ultra vires. An incorporated company is an independent legal entity with an existence separate from the existences of the total of its members. It does not die when its members die.

Most people are aware of the alternative legal device for securing perpetuity in the holding of property for collective objects—namely, the appointment of trustees who form a sort of hedge in which new plants can be inserted from time to time as the old die off. The system of incorporated companies dispenses with the system of trustees. Corporateness was anciently regarded as a privilege or concession which the Crown would award to particular bodies for good reasons. Cities and boroughs, universities and colleges, and a few commercial undertakings like the East India Company were favoured recipients. Many ancient hospitals can show their Royal Charters of incorporation; the younger institutions are less fortunate. But the old restrictive idea of corporateness as a Royal concession has been found inconvenient. In the nineteenth century a new mass-production corporateness became possible by the mere registration of a few members of an association at Somerset House under a series of Companies Acts. A remarkable development of commerce and industry has resulted. The value of the new principle is not confined to enterprises conducted for profit.

Birmingham and Midland Skin Hospital.—On July 10th a new hospital for in-patients, with modern equipment, including a department for the treatment of cancer, will be opened in Edgbaston, and the present quarters in the city will be used only for out-patients. About £10,000 is still required for the new hospital, of which £6000 is for the cancer department.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

CHANGES AT GLASGOW

THE retirement of no fewer than five professors from the University of Glasgow was intimated at a meeting of the university court last week, and three of these are medical men—namely, Prof. T. H. Bryce, F.R.S., of the chair of anatomy; Prof. Andrew Hunter, of the chair of physiological chemistry; and Prof. Peter Paterson, of the chair of surgery. Sir Robert Rait, principal of the University, in paying tribute to the retiring professors, said that Prof. Paterson had occupied the St. Mungo chair of surgery since 1924, and that the University was deeply indebted to him for the skill and devotion which he had brought to the teaching of surgery in the Royal Infirmary. Prof. Andrew Hunter came from the University of Toronto in 1929 to succeed Prof. E. P. Cathcart in the Gardiner chair of physiological chemistry; he is now returning to Toronto. Prof. Bryce had been working in the department of anatomy since 1890, and had been head of the department since 1909. In addition to his well-known anatomical work, he had done memorable service to the science of anthropology and to the study of archæology.

It was announced that the court have appointed Dr. G. N. Wishart, at present lecturer in physiology, to succeed Prof. Hunter in the chair of physiological chemistry.

HOURS OF WORK FOR NURSES

At a meeting of the health committee of Glasgow corporation last week a proposal was considered which would limit the hours of nurses in attendance in the various corporation institutions to 48 per week, and in mental institutions to 42 per week. It was pointed out that the proposed alteration would necessitate the employment of over 600 extra staff, at a cost of £185,000. After discussion an amendment was carried which stated that the committee agreed to the principle of 48 hours per week for fever and general hospitals, and that they remit back the proposal to limit hours to 42 in mental institutions, and consult with the trade-union officials interested.

ILLEGIBLE WRITING A PENAL OFFENCE

Mr. A. B. Gilmour, who is superintendent of the Central Checking Bureau in Scotland under the National Health Insurance Act, in an address to members of the Glasgow Rotary Club raised the possibility of legal action being taken against doctors who write prescriptions illegibly. He referred to a recent instance in the north of Scotland when a poison had been wrongly read in a prescription, and said that such errors suggested that it might be necessary to have a law in this country similar to a law in Norway, under which the illegible writing of prescriptions was a punishable offence.

Guy's Hospital.—The annual report of Guy's Hospital for 1934 lays stress on the urgent need of additional accommodation for the nursing staff and the staffing of Nuffield House, towards the erection of which Lord Nuffield gave £65,000. The block, which it is hoped to open this autumn, will accommodate 75 paying patients. The report speaks of an increase of support from the public which, with strict economy within the hospital, has resulted in an improvement in the hospital finances. There is no available surplus, however, from which funds could be drawn for the provision of further accommodation for nurses. Another pressing necessity is for the enlargement of the hospital dispensary.

PANEL AND CONTRACT PRACTICE

South Africa and Health Insurance

THE question of adopting some form of national health insurance has during recent years been much discussed in the overseas dominions, where it has been reported upon by several Royal Commissions. In South Africa particularly it has lately been much to the fore in medical circles, and during the present year its advantages and disadvantages have been considered at some length in the *S.A. Medical Journal.* A leading article in its issue of May 11th refers to the decisions adverse to health insurance recently adopted by the American Medical Association, the special report of the A.M.A. being reproduced in the same issue. This report is evidently regarded as a warning to South African doctors, and importance is apparently attached to statistics published by the A.M.A. purporting to show that the death-rates from certain diseases are higher in countries that have adopted State health insurance schemes than in America, which has no such scheme—ergo, health insurance does not conduce to a healthy community. It is a little difficult to imagine how such an argument came to be advanced or why it is thought to be worthy of mention. Stranger still is a long quotation from the March issue of *Colorado Medicine,* which includes the statement that "in the sickness-insurance-ridden countries of Europe, after years of experience, there now are developing more and more appeals for an abandonment of the scheme, and in favour of a return to individual responsibility." Over against this statement may be set the fact that the area of compulsory health insurance is increasing in Europe; within the last three years, for instance, the Danish scheme has been transferred from a voluntary to a compulsory basis. We would respectfully suggest that if doctors in the dominions wish to make a serious study of the practical working of national health insurance and its effects on medical practice information may profitably be sought in countries in which it is in operation. The British system, which has stood the test of 23 years' experience, including the exacting war years, was framed largely on lines laid down by the medical profession, and on its medical side is to a large extent administered by the profession. From a careful study of this scheme, its merits and its demerits, lessons on health insurance may be learnt. In South Africa the question is complicated by the existence of a native population outnumbering the European population by about ten to one; in such a community the problem of providing adequate medical services for all who need it, and adequate remuneration for the practitioners giving those services, must be peculiarly difficult to solve. But problems still more difficult have been successfully solved in South Africa, and we have no doubt that the provision of medical care to the satisfaction of the public and the profession will yield to energetic attack.

Essex Public Medical Service.

The eleventh annual report of this service shows good progress. The subscriptions which in previous years had increased by about £20–£25 weekly each year rose by £45 in 1934. At the end of the year there were 319 (doctor) members of the scheme, 254 active and 65 honorary, while 7271 new (patient) subscribers were registered during the year. At Dec. 31st, 1934, after deducting cancellations there were 14,866 books on which payments were being made, an increase of 2134 over the previous year: these books represented 26,095 subscribers—13,814 adults and 12,281 children. Sixty-one applications for assistance from the appliances fund (hitherto miscalled the benevolent fund) were approved; they ranged from surgical belts and the like to ambulance charges, nursing and massage. The revenue authorities having decided that the "profits" of public medical services are liable for income tax, the surplus to the end of 1933, of which £775 16*s.* was calculated as due to members, has been distributed to them to include in their income tax returns, with the exception of a nominal amount carried forward to the next distribution, which in future will be effected yearly.

PUBLIC HEALTH

The Housing Bill: Age and Air Space

IN a letter to the *New Statesman* of June 8th, Prof. Ralph Picken suggests, very reasonably, that the main object of the prevention of overcrowding is the promotion of the public health. He points out that although exception has been taken, during the passage of the Housing Bill through the House of Commons, to the failure to exclude living rooms in measuring the permissible occupancy of a house, the existing practice of differentiating between adults and children in the allowance of air space has been perpetuated. Thus, for this purpose, an adult is a unit, a child between 1 and 10 years of age half a unit, and an infant under a year a cipher. Prof. Picken observes that at one time preventive medicine was influenced by the idea that the evil effects of overcrowding arose from air starvation and so it was deemed that "a child naturally needed less air than a full-grown person." Yet, as he says, the most clearly demonstrable effect on health of overcrowding within houses is the greater opportunity it affords for the spread of infection, and he notes with approval the prominence which was given in the daily press to those portions of the latest annual review of the Registrar-General which stressed the association of overcrowding with high mortality from diseases of the respiratory system amongst children in towns especially.

In one of those admirable studies in field epidemiology for which the public health department of Glasgow is conspicuous, C. M. Smith,[1] investigating housing conditions and respiratory disease, found that the attack-rate per thousand of acute respiratory infections during an influenza epidemic was 340·0 among children under 5 years of age, as compared with 234·2 at all ages. During the non-epidemic part of the year the same age-group experienced the greatest incidence of acute respiratory disease.

Smith suggests that when conditions, such as respiratory diseases, which are disseminated by droplet infection are under consideration, overcrowding should be assessed on the standard of sleeping arrangements. Among those who have to deal with children, sick or well, as human beings and not as units in a scheme, opinion is unanimous about the overwhelming importance, as causes of morbidity and mortality, of acute infections of the upper respiratory and respiratory tracts, especially those of so-called influenzal type. Further, in face of the recorded mortality-rates, opinion could not be other than unanimous that these infections are lethal inversely as the age of the child attacked. Whether the sleeping quarters of a child be bedroom, dormitory or, for the time being, the ward of a children's hospital, none amongst the instructed will be found to underrate the macabre part which overcrowding plays in the dissemination of infections of the respiratory tract.

---

[1] Med. Res. Council, Special Rep. Series, No. 192, 1934.

The results in a children's ward where in the matter of cot-space an infant was deemed to be of no account and a child under 10 years of age to require only half the space of his neighbour 2 years older may be imagined. They are not likely to be described since such an arrangement would be the negation of sane administration. The child in the overcrowded home to-day is the children's hospital patient to-morrow. It would appear, if the discriminating provisions of the Bill are maintained, that only when he joins one of those republics of sick children will justice to his requirements of air space be done, possibly when it is too late to save his life.

The M.O.H. and Diets

As adviser to health, education, and maternity and child welfare committees, the medical officer of health is expected to have a precise knowledge of the nutritional value of the articles of food of which dietaries are comprised. As administrative officer in charge of a staff, one of whose duties is to assess the nutritional state of children, he must have definite ideas as to the value of the several standards of nutritional normality or abnormality in current use. The literature on these subjects is voluminous. New discoveries or theories can be followed in medical and scientific journals, but naturally writers devote special attention to the topics which are of primary interest to themselves, and the unspecialised reader is hard put to sift the ephemeral from the genuine article. Text-books, on the other hand, are apt to be out of date soon after they are published, so rapid are the additions to our real knowledge. Even the very valuable reports and memoranda of the Ministry of Health and various committees, national and international, which have been issued in recent years fail to cover all the ground required by an officer engaged in the multifarious duties of modern public health. A balanced and concise statement of present-day views was wanted, and the need has been admirably met by a report just issued from the public health department of Glasgow.[1] Dr. Seiler, who is responsible for it, has had the advantage of the advice and guidance of Prof. E. P. Cathcart, so that the review may be regarded as authoritative. It has been prepared primarily for the use of the Glasgow Health Department, but Dr. A. S. M. Macgregor, medical officer of health, hopes that it will be of service to the departmental committee on Scottish Health Services. If it is made available it should find many readers outside these circles, for there is no other publication of the size which deals so thoroughly with all the established facts and recent work bearing on foods, the substances of which they are made up, the mode of measuring requirements of energy and replacement, the assessment of malnutrition, and the application of this knowledge to the practical problems of health. For those who desire to pursue further any of the matters dealt with, 108 references to original writings are given.

No one but the specialist can carry all this material in his memory. The survey should be read carefully by those who can obtain it, but it should prove even more valuable to medical officers of health for reference in the preparation of reports, and in facing the sometimes tendentious questions and criticisms of lay members of committees.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 8TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2072; diphtheria, 943; enteric fever, 27; acute pneumonia (primary or influenzal), 1126; puerperal fever, 49; puerperal pyrexia, 131; cerebro-spinal fever, 24; acute poliomyelitis, 4; acute polio-encephalitis, 1; encephalitis lethargica, 9; dysentery, 22; ophthalmia neonatorum 108. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 14th was 2897, which included: Scarlet fever, 930; diphtheria, 1105; measles, 40; whooping-cough, 354; puerperal fever, 34 mothers (plus 11 babies); encephalitis lethargica, 269; poliomyelitis, 2. At St. Margaret's Hospital there were 14 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 20 (0) from measles, 3 (1) from scarlet fever, 26 (2) from whooping-cough, 20 (3) from diphtheria, 30 (15) from diarrhœa and enteritis under two years, and 60 (4) from influenza. The figures in parentheses are those for London itself.

Blackpool reported the only fatal case of enteric fever. Three deaths from measles occurred at Liverpool and Birmingham. No great town, except London, reported more than a single death from diphtheria. Of the deaths attributed to influenza 5 occurred at Sheffield, 4 at Bradford.

The number of stillbirths notified during the week was 263 (corresponding to a rate of 38 per 1000 total births), including 36 in London.

SOUTH-EASTERN HOSPITAL FOR CHILDREN, SYDENHAM.—The Duchess of Kent recently opened the new wing of this hospital, which has been built and equipped at a cost of £28,000. It has increased the number of available beds from 72 to 100 while releasing wards in the old building for administrative purposes. It also includes X ray, sunlight, and casualty departments and four single bed wards for private patients. Last year the institution dealt with 33,000 out-patients and 1500 in-patients.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A second "refresher" course in medicine, surgery, and the specialties will be given at the Prince of Wales's Hospital, from July 1st to 13th. Other forthcoming courses include proctology at St. Mark's Hospital (July 1st to 6th), urology at the All Saints' Hospital (July 8th to 27th), general medicine and surgery at the Southend Hospital (July 13th and 14th), dermatology at the Southend Hospital (every afternoon from July 15th to 27th). A special demonstration on the fundus oculi will be given by Mr. R. Lindsay Rea, on Tuesday, July 2nd, at 8.30 P.M., at the in-patient department of the West End Hospital for Nervous Diseases. A panel of teachers is prepared to give individual instruction in various branches of medicine and surgery, daily. With the exception of the cardiology course, courses and clinics arranged by the fellowship are open only to members and associates. The secretary of the fellowship may be addressed at 1, Wimpole-street, London, W.1.

---

[1] Diet and Nutrition. A Survey of Recent Work. By H. E. Seiler, M.D., D.P.H., Senior Assistant Medical Officer, Public Health Department, Corporation of Glasgow. Pp. 48.

OBITUARY

WILLIAM EDWARD HOME, B.Sc., M.D. Edin., O.B.E.

FLEET-SURGEON, R.N.

THE death occurred at Southborough, Kent, of Fleet-Surgeon Home whose forcible pleas for improvement in many directions of the mercantile marine will be familiar to our readers.

William Edward Home was born in 1860 and had a fine medical lineage, for both his great grandfather and his grandfather were professors of materia medica in the University of Edinburgh, and both became presidents of the Royal College of Physicians of Edinburgh. Home's father, William Lewis Home, was an officer in the Army Medical Services, and served in China, Mauritius and the Crimea. His mother, Miss Charlotte Grome, died shortly after his birth, and he was only 16 when he lost his father. He received his general education at Rugby and entered the University of Edinburgh, where he read in the science schools, and graduated as B.Sc. in 1882. He then proceeded for his medical course and took the degrees of M.B., C.M.Edin. in 1885, and entered the medical service of the navy immediately and served with the Duke of Edinburgh—later Duke of Saxe-Coburg and Gotha—on the Mediterranean flag-ship *Alexandra*. On the *Thrush* and the *Melampus* he had as a brother officer H.M. King George. He was now to see active service for as surgeon to the *Swallow*, on the Cape and West Africa station, forming part of a naval brigade sent out for the purpose, he took part in a punitive expedition to punish a robber chief at Zanzibar, and he received the General African Medal in 1893 with the Vitu clasp. He was promoted staff surgeon in 1897, and in 1900 served during the China war and received the China medal. He was appointed in 1897 staff surgeon to the *Tamar* at Hong Kong, and became fleet surgeon in 1901. Hospital appointments at home followed, and he retired from the service in 1911 with the decoration, O.B.E.

[Photograph by Army & Navy Auxiliary C.S.

FLEET-SURGEON W. E. HOME

Fleet-Surgeon Home now left England for British Columbia, and from 1912 to 1916 was on the staff of the Victoria Hospital, B.C., and bacteriologist to the hospital. He resigned that post in 1916 and returned to England to take a commission in the R.A.M.C., and with the rank of temporary major served in the R.A.M.C. for seven years. During the war he was mainly engaged in transport operations on board the hospital ships *Warilda*, *Glenart Castle*, *Essequibo*, *Dongola*, and others, and became deeply interested in the hygiene of ships and the precautions taken for due sanitary care of the crews. At the termination of hostilities, he continued to serve in military hospitals, among others Cosham for three years, finally retiring in 1923. His impressions derived during the war led him to become a candid critic of the sanitary provisions made for the men of the mercantile marine, and he wrote in these columns many valuable articles on the subject, some of which were incorporated in a book, published in 1921 entitled, "Merchant Seamen, their Diseases and their Welfare Needs." There is no doubt that the mercantile marine owes a great deal to Home, for he pointed out many places in which reforms were necessary, and although his writing was always of a downright character, he testified invariably to the goodwill of the ship owners, though he was impatient with the attitude of the Board of Trade. He had the right reforming spirit, while in the various articles which he wrote for THE LANCET he spared no pains in his personal investigations of various ships to be accurate, to commend what deserved credit, and when criticising faulty conditions to give full reasons for his strictures. This he was able to do from a strong position, for he used all opportunities to keep abreast of medical progress, by reading, reviewing, and attendance at many medical societies.

Home was an invalid at the latter end of his life, and recently had undergone a severe operation, but to the end remained courageous and interested in the work which he had set himself. He married in 1896 Ida Mary Geraldine Richardson, a niece of Admiral Sir Frederick Bedford, who was Commander-in-Chief at the Cape when Home was on the *Swallow*; she survives him but there were no children of the marriage.

The portrait represents him at the age of 56, when he joined the R.A.M.C.

CHARLES ROBERTS, M.B. Lond., F.R.C.S. Eng.

CONSULTING SURGEON, MANCHESTER ROYAL INFIRMARY

THE death occurred on Sunday, June 9th, of Mr. Charles Roberts, the well-known Manchester surgeon. He received his medical education at the Middlesex Hospital, where he gained an entrance scholarship, and he graduated with honours as M.B., B.S. Lond. in 1896, in which year he also took the English double diplomas. He continued to secure a series of prizes and exhibitions at the hospital in medicine, surgery, and obstetrics, and obtained the F.R.C.S. Eng. in 1899. He filled all the resident appointments at the Middlesex Hospital, where he was casualty officer at the time of the outbreak of the South African War. Here he saw hard service as civil surgeon with the South African Field Force. At the close of hostilities he began his long career at Manchester with the appointment of resident surgical officer at the Manchester Royal Infirmary. He also lectured on clinical and practical surgery in the medical school of Manchester University, and in 1911 was appointed surgeon to the infirmary and at the same time to the Manchester Children's Hospital at Pendlebury. At the outbreak of the European war he went out to France with the 1st Expeditionary Force and served through the earliest stages of the campaign with the 18th Field Ambulance.

Roberts remained on the active staff of the infirmary until 1934 when he attained the age limit of 60, and his retirement followed to the regret of all associated with him and the institution. He did not write much and only from the standpoint of personal experience. To our columns he contributed a descriptive article on operations for ectopion vesicæ, to the *Middlesex Hospital Journal* one on surgery in the

Boer War, and to the *British Medical Journal* an article on the treatment of abdominal wounds in war, also from experience gained in South Africa. But although he wrote little he gained a high reputation as a teacher, as a general surgeon, and perhaps particularly as a pædiatrist. He was a member of the Association of Surgeons of Great Britain and Ireland, and his colleagues recognised him as a fine exponent of surgery.

JOHN STOKES, M.D. Durh., LL.B. Sheffield

THE medical profession and a large number of friends and patients have learned with regret of the death of Dr. John Stokes, late consulting physician to the Sheffield Children's Hospital. He received his education at the Sheffield Grammar School and at the universities of Sheffield, London, and Durham, and graduated in two faculties, those of law and medicine, being B.Sc. Lond., LL.B. Sheffield, and M.D. Durh. He qualified in medicine in 1887 and 20 years later was called to the Bar at the Inner Temple. He was, as this brief record shows, a man of great energy and varied interests and especially in the masonic world was he a prominent personality. He was a Past Master of several lodges and of the Quatuor Coronati, ten years ago he was Grand Deacon of England, and in 1928 became Deputy Provincial Grand Master. His long and distinguished masonic work brought him into touch with a number of influential people and his funeral was remarkable for the number of attendants, representing the medical profession, different universities, freemasonry and archæology, as well as personal relations.

JOSEPH H. ENSOR TROUT, L.R.C.P. Edin.

Dr. Ensor Trout, who died last week at his home in Edgbaston at the age of 71, was the son of a working jeweller and first studied medicine as page in a doctor's surgery. Coming under the notice of Mr. Lawson Tait he was sent to Mason College and went on to Surgeons' Hall, Edinburgh, from which he took the Scottish triple qualification in 1894 with honours in anatomy. After qualification he returned to Birmingham as resident surgical assistant at Queen's Hospital, obtained some experience of general practice as an assistant and then set up for himself at the corner of Ingleby Street and Monument Road where his surgery remained for 50 years. In pre-National Insurance days it was said that he had the biggest working-class practice in England. In one street alone, he was once heard to say, enough money was owing to him to have bought him a Rolls Royce. Early on he became surgeon to Piggott's engineering works and as time passed he became attached to various branches of group practice. As "vet" to the Bostock menagerie he once rode through the streets to the Weston Road Institution—he was one of the oldest members of the Birmingham board of guardians—on the back of an elephant. During the war he undertook to give free medical service to the wives of men who joined the Army from the district in which he practised. His personal popularity was great throughout Birmingham and was perhaps enhanced by his extraordinary resemblance to a well-known politician. Dr. Trout married 43 years ago Miss Helen Elizabeth Abell, theatre sister to Mr. Jordan Lloyd. His only son Mr. Lawson Trout, to whom we owe many of these interesting particulars, is the godchild of Lawson Tait.

BERNARD D. Z. WRIGHT, M.R.C.S., L.R.C.P.

Bernard Duncan Zorapore Wright, although he had recently retired from practice, was very well remembered by a large circle in Norfolk. His death occurred at his house at Hoveton St. John on June 10th, and was a sequel to serious operations. Born at Canterbury, the son of John William Zorapore Wright, he was educated at Rugby and proceeded for his medical education to St. Bartholomew's Hospital. He took the English double diploma in 1907 and practised all his life in Norfolk. He came to the county as a locum tenens immediately on registration and until two years ago was practising at Coltishall. He was a valuable and energetic worker in the cause of the Norfolk and Norwich Hospital, was for many years a member of the management committee and for a time its chairman. A coöpted member of the Norfolk County Council he served on the county insurance committee and was chairman of the panel committee. He was also, for many years, M.O.H. for the Smallburgh R.D.C. Dr. Wright's public services, it will be seen, were many and valuable, and his death has given rise to wide regret in the county of Norfolk.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. F. C. Wright to *President* for further course, and to *Drake* for R.N. Hospital, Plymouth.

Surg. Lt. C. N. H. Joynt to *President* for course.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdrs. C. C. Elliott and H. Parry-Price to *Tiverton*.

Surg. Lt.-Comdrs. R. H. Enoch to *Royal Sovereign*; R. B. H. Wyatt to *Tiverton*; and J. L. Cox to *Tiverton*.

Surg. Lts. R. D. Bradshaw promoted to Surg. Lt.-Comdr.; J. F. Heggie to *Tiverton*; and R. W. G. Lancashire (proby.), to R.N. Hospl., Chatham.

CORRESPONDENCE

MALARIA AND RACIAL EXTINCTION

To the Editor of THE LANCET

SIR,—Your leading article of May 25th expresses a hope that the Government of North Borneo will now undertake work to save the Muruts. I need hardly say that I share this hope. The immediate distribution of large quantities of quinine and Euquinine, especially amongst women of child-bearing age, and children of all ages, will stay the present rapid decline in population, and will also be an encouragement to the natives to coöperate in rural sanitary measures, the reason for which they cannot be expected to understand. Incidentally I may remark that the ultimate responsibility for the welfare of the natives of North Borneo rests upon His Majesty's Government; for Section 10 of Queen Victoria's Charter requires :—

> "If at any time Our Secretary of State thinks fit to dissent from or object to any part of the proceedings or the system of the Company relative to the people of Borneo or to any of the inhabitants thereof in respect of slavery or religion or the administration of Justice or other matter and to make to the Company any suggestion founded on that dissent or objection the Company shall act in accordance therewith."

You make one statement, however, which I cannot allow to go unchallenged—namely, that "the decrease in native populations is often due to subtle influences of an imponderable psychological character." On reading these words I could only ask myself whether this was indeed the twentieth century or whether we were living once again in the world of vital spirits, humours, effluvium, animal magnetism, and miasma. The recollection of these old dogmas—I had thought them safely in their tombs—was succeeded by a vision of dejected diseased little Muruts, waiting to beg exemption from a crushing poll tax. The invocation of imponderable influences seems scarcely necessary when other factors are so obvious, and by way of illustration there is no need perhaps to go further than two passages from current literature :—

> "When circumstances are such that an infection can saturate almost the entire population of crowded regions, the result is what the Germans call *Durchseuchung*. The accidentally less susceptible survive. . . . The simplest demonstration of such changes is the rapidity of spread and the virulence of a disease when it is first introduced into the reservoir of an aboriginal—that is, entirely susceptible—population. When measles first came to the Fiji Islands in 1875, as a result of the visit of the King of the Fijis and his son to Sydney in New South Wales, it caused the death of 40,000 people in a population of about 150,000. Another example is the terrific violence of small-pox when first introduced among the Mexican Indians by a Negro from the ship of Narvaez. The virulence of tuberculosis for Negroes, Eskimos, and American Indians living in contact with whites is another case in point. Any number of illustrations of this kind might be cited."[1]

> ". . . in the case of British Guiana . . . nothing in the way of hinterland development . . . has been a lasting excuse for the wiping out of the aborigine . . . the Indians had contracted various diseases, among which influenza was the most devastating. He caught influenza, but there was no medicine left behind for him, so he and often his entire family took to their hammocks and quietly died."[2]

I am, Sir, yours faithfully,

Whiston-street, E., June 15th. A. J. COPELAND.

AUSCULTATORY PERCUSSION IN ASCITES

To the Editor of THE LANCET

SIR,—In an interesting annotation under this title in your issue of Oct. 27th, 1934 (p. 938), you describe this auscultatory phenomenon as the "double bruit ascitique" of Lian and Odinet. I have also observed these same sounds in cases of ascites and published my results (Jour. Amer. Med. Assoc., March 21st, 1931) before Lian and Odinet's original publication on this subject appeared in 1931 (Soc. méd. des hôp. de Paris, July 10th). I am not attempting to claim priority, since I think the value of the sign is only of a confirmatory nature. I should like to make the point, however, in order to avoid confusion, that this physical sign, if included in text-books of physical diagnosis, should be described on the basis of its own properties and not associated with the name of the doctor who first observed it.

I am, Sir, yours faithfully,

J. THORNWELL WITHERSPOON.

Indianapolis, Indiana, June 6th.

CORONARY THROMBOSIS—THE FIRST YEAR AFTER

To the Editor of THE LANCET

Footprints, that perhaps another
A forlorn and shipwrecked brother,
Seeing, may take heart again.

SIR,—Whether the dinner or the speeches, or a combination of both was the exciting cause, is a matter of speculation, but the fact remains that it was during the after-dinner speeches at the Association of Surgeons' meeting in 1934 that the occlusion occurred. To a victim of coronary thrombosis who has read the article in THE LANCET[3] on the Prognosis in Coronary Thrombosis, the outlook is distinctly gloomy and depressing as regards the limitation of both life and its activities. I owe a debt of gratitude

THE SERVICES (*continued from previous page*)

No. 2 Central Medical Board; T. V. O'Brien to Aircraft Depôt, Karachi, India, for duty as medical officer.

Flight Lt. C. Crowley to Central Medical Establishment.

Flying Offr. J. W. Patrick to No. 1 School of Technical Training (Apprentices), Halton.

INDIAN MEDICAL SERVICE

Capt. C. L. Ahluwalia relinquishes his temp. commn.

Capt. P. Shannon, I.M.S., has been awarded the North Persian Forces memorial medal for 1934 for his paper on A Study of Trachoma in Baluchistan, published in the *Indian Medical Gazette* of December, 1934.

COLONIAL MEDICAL SERVICE

Dr. J. M. Liston has been appointed Medical Officer, Kenya, and Dr. P. E. F. Routley Medical Officer, Malaya. Drs. D. S. Johnston and A. J. Murray become Medical Officers, Gold Coast; Dr. R. C. Jones Health Officer, Hong-Kong; Dr. L. V. P. Goupille Medical Officer, Hookworm Branch, Mauritius; and Dr. J. R. Pierre Assistant Radiologist, Mauritius.

to "Live and Learn" for recounting his more cheering experiences entitled Coronary Thrombosis and after, and it is with the hope that I in turn may bring cheer and comfort to another like sufferer that I am now recording my own history for the first year.

Being a surgeon, aged 50, it was necessary to continue at work to earn the weekly housekeeping and educate my sons. I was looked after by a physician who called in a professor of physic particularly well versed in the vagaries of coronary occlusions. "Bed for six weeks," said he, "and a complete rest for four months, then work at half speed till the end of the year." This I did faithfully, even to staying abed for seven weeks so as to be on the safe side. The result has been most gratifying, for when in May, 1935, he applied all his tests, ancient and modern, he asserted, and I believe truthfully, that he could find nothing amiss with the old pump.

There are a few rules which I have laid down for myself. Perhaps it is neurasthenia, but I imagine I do not feel as fit if I break any of them.

1. Breakfast in bed on Sundays.
2. Bed about 10 P.M.
3. Never to operate for more than three hours at a stretch.
4. An hour's sleep twixt lunch and dinner, unless absolutely impossible, for I must confess to becoming more easily tired than of yore.
5. No smoking till after dinner, and then one cigar. (All my old pipes have been thrown away.)
6. No more old brandy or port, only beer and occasional sherry.

So much for restriction, but despite these, life has not been dull. My broad-minded physicians allowed me to go out cub-hunting for a couple of hours at a time in September. Here I was prepared to argue as follows: if I am allowed to walk on my own two legs, may I be allowed to sit on my horse while he walks on his four legs! But there was no need for argument, my petition was granted, and on Nov. 1st I was allowed to go a-hunting. True my horse was taken on for me, and I only stayed out for two hours, but the pleasing fact remains that I was allowed to continue riding to hounds, and that without any ill-effects. Hunting one day a week, I was one of the lucky few who finished what was probably the best run of the season on an 8 mile point. Gradually staying out longer, on the last day I stayed out till hounds went home.

As ski-ing ("Live and Learn") and hunting are somewhat beyond the activities generally laid down for coronary occlusionists, I tell my tale not to incite others to be rash and do things beyond their more limited powers, but to show that with due care one can still work and derive pleasure out of life without being an altogether passive invalid.

I am, Sir, yours faithfully,

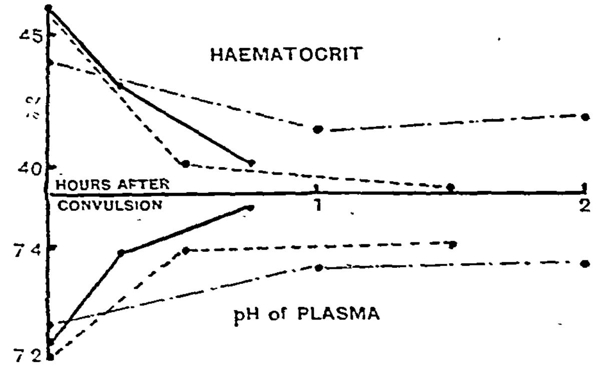
June 14th. AGAG THE SECOND.

WATER METABOLISM IN EPILEPSY

To the Editor of THE LANCET

SIR,—May I comment on two papers appearing in your last issue? In the first Drs. Fletcher and Peden report that the hæmatocrit (i.e., the percentage volume of the blood occupied by red corpuscles) is abnormally variable in epileptic subjects. Some years ago I made a few measurements of the pH of the plasma during and at short intervals after convulsions in an epileptic girl, and as the technique involved determination of the hæmatocrit, my notebook throws some light on the above question. In the accompanying diagram I have plotted out successive readings of pH and hæmatocrit obtained in three convulsions. The hæmatocrit of the patient between convulsions was usually about 40 per cent.

Two things seem clear from this chart: (1) that the hæmatocrit is slightly raised at the height of the convulsion, and afterwards falls gradually back to normal, and (2) that this change bears rough comparison with the pH curve. I also observed similar but more marked changes in rabbits during insulin convulsions. The explanation of these fluctuations is not difficult. During epileptic convulsions increased muscular work and respiratory embarrassment combine to cause considerable temporary acidosis, and it is well established that acidosis leads to transfer of fluid from plasma to corpuscles. I conclude that the variations observed by Drs. Fletcher and Peden are due to this tendency for the hæmatocrit to rise during convulsions, a rise which simply represents swelling of red corpuscles exposed to a falling pH, and which may be dismissed as a mere consequence of the convulsion.



In passing, I should like to point out that the loss of extracellular body fluid during convulsions was first described, not by myself as Drs. Fletcher and Peden imply, but by Gamble and Hamilton (Bull. Johns Hopkins Hosp., 1927, xli., 389).

The second paper, by Drs. Clegg and Thorpe, confirms earlier American claims that the combined administration of pitressin and water to provoke convulsions may sometimes be useful in the diagnosis of epilepsy. I think it should be pointed out, however, that the test is not free from danger. In one case reported by McQuarrie (Amer. Jour. Dis. Child., 1929, xxxviii., 451) this procedure precipitated (or at least was immediately followed by) status epilepticus, from which the patient was only rescued by the prompt use of diuretics. Foerster has shown that fits can be provoked in the epileptic by voluntary overbreathing (Deut. Zeits. f. Nervenheilk., 1924–25, lxxxiii., 347). Perhaps this would prove a simpler and safer alternative to the pitressin-water test.

I am, Sir, yours faithfully,

F. B. BYROM.

Bernhard Baron Institute of Pathology,
London Hospital, E., June 18th.

ST. VINCENT'S ORTHOPÆDIC HOSPITAL, EASTCOTE.—This institution under the charge of the sisters of St. Vincent de Paul proposes to rebuild the old wards and the operating theatre at a cost of £25,000. During 25 years at Eastcote, in Middlesex, over 16,000 cases have been received. The average stay of a patient is over one and a half years.

Primary Fellowships.—Anatomy: Mr. Grant Massie, Mr. P. N. B. Odgers, Prof. H. H. Woollard, and Prof. R. B. Green. Physiology: Prof. G. A. Buckmaster, Dr. D. H. de Souza, Prof. Samson Wright, and Prof. Hamilton Hartridge.

Diplomas of L.R.C.P., M.R.C.S.—Elementary Biology: Mr. G. P. Mudge, Mr. C. C. Hentschel, Mr. A. J. Grove, and Mr. W. A. Cunnington, D.Sc. Anatomy: Mr. E. P. Stibbe, Prof. Lambert C. Rogers, and Dr. A. J. E. Cave. Physiology: Prof. A. St. G. J. McC. Huggett, and Prof. Samson Wright. Midwifery: Mr. L. Carnac Rivett, Mr. Malcolm Donaldson, Mr. A. C. Palmer, and Mr. Victor Lack. Pathology: Mr. C. E. Shattock, Mr. Robert Davies-Colley, Prof. James McIntosh, and Prof. William Bulloch.

Diploma in Public Health.—Part I.: Prof. C. C. Okell. Part II.: Dr. James Fenton.

Diploma in Tropical Medicine and Hygiene.—Colonel W. P. MacArthur and Dr. G. Carmichael Low.

Diploma in Ophthalmic Medicine and Surgery.—Part I.: Mr. C. Bernard Goulden and Mr. Leighton Davies. Part II.: Mr. R. Foster Moore.

Diploma in Psychological Medicine.—Dr. F. L. Golla.

Diploma in Laryngology and Otology.—Part I.: Mr. E. Musgrave Woodman and Mr. Sydney Scott. Part II.: Mr. T. B. Layton.

Diploma in Medical Radiology.—Part I.: Prof. J. M. Woodburn Morison. Part II.: Dr. J. H. D. Webster.

Diploma in Anæsthetics.—Dr. H. E. Gaskin Boyle.

The following hospitals were approved, with the posts specified, for recognition for the six months' surgical practice, required of candidates for the final examination for the fellowship.

England.—Birkenhead General Hospital (senior house surgeon); St. Luke's Hospital, Bradford (2 house surgeons); Royal Infirmary, Chester (3 house surgeons); Chesterfield and North Derbyshire Royal Hospital (resident surgical officer and 3 house surgeons); Coventry and Warwickshire Hospital (4 house surgeons); Derbyshire Royal Infirmary (for one year, 3 senior house surgeons); Dewsbury and District General Infirmary (first house surgeon); Herefordshire General Hospital (resident medical officer); East Suffolk and Ipswich Hospital (first and second house surgeons); Mill-road Infirmary, Liverpool (senior resident surgical officer); Walton Hospital, Liverpool (senior resident assistant medical officer for surgery); National Temperance Hospital, London (resident medical officer and 1 house surgeon); Northampton General Hospital (temporary recognition, 2 house surgeons); North Staffordshire Royal Infirmary, Stoke-on-Trent (for one year, 3 house surgeons); Royal Albert Edward Infirmary, Wigan (resident surgical officer and first house surgeon).

Abroad.—The General Hospital, Adelaide (house surgeons); The General Hospital, Auckland (house surgeons); Christchurch Hospital (house surgeons); Dunedin Hospital (house surgeons); Melbourne Hospital (house surgeons); Alfred Hospital, Melbourne (house surgeons); St. Vincent's Hospital, Melbourne (house surgeons); Perth Hospital (house surgeons); Sydney Hospital (house surgeons); Prince Alfred Hospital, Sydney (house surgeons); St. Vincent's Hospital, Sydney (house surgeons: and The General Hospital, Wellington (house surgeons).

Royal Faculty of Physicians and Surgeons of Glasgow

The following have been admitted to the fellowship of the faculty:—

David Fyfe Anderson, M.B. (Glasgow); Christian Melville Fleming, M.D. (Glasgow); Evelyn McPherson, M.D. (Glasgow); Ian Scott Smillie, M.B. (Helensburgh); and Frank Lyth, L.M.S.S.A. (Manchester).

University of Bristol

At recent examinations the following candidates were successful:—

M.D.

J. F. Coates (with distinction), H. F. M. Finzel, and J. P. P. Stock.

FINAL EXAMINATION FOR M.B., CH.B.

Section I. (including Forensic Medicine).—R. D. Cæsar, Coralie W. Rendle-Short, and Paul Zimmering, and Centa Alkan and Ursula G. Hewitt (in Section I. only).

Section II.—Kathleen G. Brimelow and S. D. Loxton (with second class honours); F. C. Collingwood, A. E. Jowett, Broughton Ridgway, and A. W. Woolley.

B.D.S.

J. W. E. Snawdon (with second class honours).

L.D.S.

R. E. Buchan, J. G. Clancy, B. E. Ffrench, Frances M. Orton, D. E. Royal, and L. E. Scull.

University of Sheffield

Dr. Francis Davies, reader in anatomy in the University of London, at King's College, has been appointed professor of anatomy in succession to Prof. C. J. Patten, who is retiring.

Dr. Davies received his medical education at University College Hospital, taking the conjoint qualification in 1922, and [illegible] 1924. Two years later he took his M.D. [illegible] of science. After a resident appointment at University College Hospital he became senior demonstrator and research worker in anatomy at University College, and in 1932 he was awarded the Symington prize for anatomy. His contributions to medical journals include papers on normal cholecystography, the conducting system of the avian, and monotreme heart and the pathology of papillœdema.

University of London

At a meeting of the senate on June 12th Mr. H. L. Eason, C.B., C.M.G., superintendent and senior ophthalmic surgeon of Guy's Hospital, was elected vice-chancellor for the year 1935–36.

University of Edinburgh

Dr. Chalmers Watson, physician to the Edinburgh Royal Infirmary, has been nominated as a candidate for the post of Lord Rector, the other nominees being the Marquis of Clydesdale, Lord Allenby, Mr. Christopher Grieve, and Mr. W. B. Yeats. The election will take place early in the autumn term.

St. Thomas's Hospital Medical School

Lord Wakefield will distribute the prizes at this school on Tuesday next, June 25th, at 3 P.M., in the governors' hall.

Central Council of Recreative Physical Training

This council has just been formed, with the cordial coöperation of the Board of Education, in order to bring together representatives of the various bodies interested in the welfare of the country's youth, and to make a survey of the facilities for recreative physical training for adolescents, men and women in the British Isles. Lord Astor is the president, and the medical members will include Lady Barrett, Sir Henry Brackenbury, Dr. Anna Broman, Sir Farquhar Buzzard, Dame Janet Campbell, Dr. Veitch Clark, Sir Louis Greig, Lord Horder, Sir W. Arbuthnot Lane, Sir Walter Langdon-Brown, Dr. Louisa Martindale, Lord Moynihan, and Sir George Newman. With data obtained from the survey it is intended to assist the trustees of the King George's Jubilee Trust, by submitting definite proposals for the coördination and development of recreative physical activities of young people of post-school age. It is hoped that a central body will be able to widen the activities of organisations already in existence, without in any way interfering with their individuality, and so help to extend the benefits of physical education and recreation to the thousands who have not yet been drawn into any scheme. The organising secretaries of the council are Mr. H. A. Cole (chief organiser of physical training, Sheffield) and Miss P. S. Colson (Ling Association). A temporary office has been opened at 11, Doughty-street, London, W.C.1.

Harveian Society of London

On June 13th members dined together at Merchant Taylors' Hall with comfort and dignity made possible by Sir Buckston Browne's munificence. Lord Palmer, who proposed "The Society" in a strain of happy congratulation ("still going strong" at well over a hundred, he said), left the president, Mr. L. E. C. Norbury, to give the material evidence of prosperity. Twenty-four new members last year, said Mr. Norbury, making a total ordinary membership of four hundred, not including 12 honorary members of whom seven were with them that night. He expressed keen regret that the society still had no home of its own; here was a chance for another benefactor. He also made a plea for wiping out the remaining deficit on the Harvey tower of Hempstead Church. Two earlier presidents of the society took the opportunity of offering gifts. Dr. Hope Gosse, president in 1934, placed on the table a bust in bronze done by his nephew of Sir Buckston Browne, and Lieut.-Colonel E. L. Gowlland, president in 1933, a copy of Rembrandt's "Anatomy Lesson" (possibly the work of the artist himself) left to him by his cousin the late Mr. Peter Gowlland, F.R.C.S., and a wonderful malacca cane containing all kinds of gadgets—lancet, catheters, hypodermic syringe—given by some Indian worthy to Sir Warren Crooke-Lawless when he was surgeon to the Viceroy. These gifts, as well as Sir Buckston Browne's picture of Harvey explaining the circulation to Charles I., emphasised the president's plea for a worthy house in which to place them. The toast of "The Visitors" was proposed by Mr. A. E. Webb-Johnson with precisely the proper combination of eulogy and malice, and response was made by the Very Rev. W. R. Matthews, Dean of St. Paul's, Dr. J. O. Wakelin Barratt, Deputy-master of the Apothecaries, and Sir Henry Curtis Bennett, K.C. The precincts of the hall, thrown open to the diners by permission of the court, made an agreeable background for social intercourse up to a late period of the night.

Royal East Sussex Hospital

A new pathological laboratory is to be built at this hospital at a cost of £6000. Ordinary expenses during the last year exceeded ordinary income by £1241.

Addenbrooke's Hospital, Cambridge

It has been decided to enlarge and improve the casualty department at this hospital, which is now too small for the greatly increased number of cases. The enlargement of the ear, nose, and throat department is also under consideration.

London Jewish Hospital

An appeal for £100,000 was to have been issued on behalf of this hospital, but on the advice of King Edward's Fund it has been decided at present to appeal for only £60,000. The present nurses' home is out of date and a new one is urgently needed. 28 per cent. of the patients are non-Jews.

St. Albans Hospital

The contributory scheme of this hospital is progressing well and there are now 7000 members. But the district is enlarging rapidly and the hospital's expenses accordingly. The accident cases present a problem and cause a great strain upon the accommodation.

Out-patient Time-table at Voluntary Hospitals

This time-table, sent out periodically by the King Edward's Hospital Fund for London, has now been revised to May, 1935. In this issue addresses of hospitals have been included as well as telephone numbers. The hope is expressed that this detailed list of hours and days for first attendance of new out-patients will facilitate the consultative use of hospital out-patient departments and reduce the period during which patients have to wait. Copies may be obtained free on request from the publishers, Messrs. Geo. Barber and Son, Ltd., Furnival-street, London, E.C.4.

Royal Medico-Psychological Association

The ninety-fourth annual meeting of this association will be held from July 3rd to 5th at 11, Chandos-street, W., and the Guildhall, Westminster, under the presidency of Dr. Reginald Worth. Dr. Worth has chosen as the title of his presidential address Four Decades of Psychiatry. Among those who will read papers are Dr. Thomas Power (modern endocrinology and mental disorder), Dr. H. C. Beccle (recent investigations in the hæmatology of the psychoses), and Dr. W. D. Nicol (clinical aspects of G.P.I.). The secretary of the association may be addressed at Springfield Hospital, London, S.W.17.

Royal Sussex County Hospital, Brighton

A festival dinner was held at the Royal Pavilion, Brighton, on June 14th, to inaugurate an appeal for £60,000 in order to provide 100 more beds. The chairman of the board of management, Brigadier-General d'A. C. Brownlow, presided. Lord Horder, in proposing the toast of the hospital, expressed particular pleasure at meeting again so many of his old pupils on its staff. He paid tribute to "this thoroughly up-to-date general hospital, a piece of machinery which ticked over noiselessly and efficiently," and welcomed the fact that within its walls there were none of those cliques or stunts which did so great a disservice to medicine. For a town of 257,000 inhabitants a hospital with only 250 beds was wholly inadequate. The chairman in response said that during the last 21 years the governor had spent over £104,000 in equipment and buildings. He announced that in donations and promises the sum of £5489 had already been received. After the Dean of Chichester and Mr. Francis Donne had spoken, Dr. Donald Hall proposed the toast of the guests. Of Lord Horder he said that his care for humanity, both living and dead, was proved by the fact that he was president of both the Anti-Noise League and the Cremation Society. Mr. J. H. Thomas, M.P., in reply, poked fun impartially at hosts and guests whose efforts to arouse enthusiasm for the appeal he affected to despise, and ended on a more serious note with a spirited defence of the voluntary hospital system and of the value of voluntary service as opposed to compulsion.

The New Poisons Code

The Home Office gives notice that the rules under Section 23 of the Pharmacy and Poisons Act, 1933, will come into force on May 1st, 1936, the date on which the relevant sections of the Act come into operation. On that date the various existing statutory provisions and regulations relating to the sale, supply, storage, and transport of poisons will be repealed. Copies of the poisons list and rules may be obtained from H.M. Stationery Office, price 8*d*.

Sheffield Royal Hospital

A convalescent home with accommodation for 48 patients is to be built for this hospital with funds provided by the Zachary Merton trust. The cost of the site, building, and equipment is being met by the trust, and it is thought that the convalescent funds of the hospital will be sufficient to bear the cost of maintenance.

Mansfield Hospital

An appeal is being made by this hospital for £40,000 to extend the institution. It is hoped to build two new wards and to provide additional nursing and domestic accommodation. Various colliery firms have already responded generously and over £3500 has been already received.

Derbyshire Royal Infirmary

The largest donation ever received by this institution has been given by members of the family of the late Mr. Samuel Gee, of Duffield, who have contributed £20,000 to the hospital for the building of a new block to be known as the Gee block.

Lady Tata Memorial Scholarships

The trustees of the Lady Tata memorial fund have awarded scholarships for 1935–36 to Dr. M. C. G. Israëls (Manchester), Dr. O. Kaalund- Jörgensen (Aarhus); and grants to Prof. W. Büngeler (Danzig), Dr. J. Engelbreth-Holm (Copenhagen), Dr. Karl Hinsberg (Berlin), Dr. Ch. Oberling (Paris), Prof. Eugene Opie (New York), and Dr. Lucy Wills (London). These awards were open to graduates of any nationality, for research work in diseases of the blood, with special reference to leukæmia.

British Red Cross Clinic for Rheumatism

The annual report for 1934 of the British Red Cross Society shows continued expansion in all sections of the Society's work. During the year there were 98,656 attendances for treatment at its clinic for rheumatism (Peto-place, London, N.W.), an increase of 4400 over 1933. Of the patients treated 45·6 per cent. were discharged completely cured or free from symptoms, 36·1 per cent. were definitely improved, and 17·1 per cent. were unchanged or slightly improved. Only 1·2 per cent. were worse after discharge. The clinic has now completed five years' work but is faced with a substantial deficit each year, and the proceeds of the annual Red Cross ball, to be held at Grosvenor House on Nov. 27th, will go to its support.

International Congress on Life Assurance Medicine

This congress will meet at the offices of the Prudential Assurance Company (142, Holborn Bars, London, E.C.) from July 24th–26th. On July 23rd, at 10 P.M., there will be a government reception at Lancaster House, London Museum, St. James's, at which the Minister of Health will receive the guests. The next morning the congress will be formally opened by the president, Sir Walter Langdon-Brown. Dr. Josef Sturm (Munich) and Dr. Chester T. Brown (Newark, N.J.) will open a discussion on methods of estimating risks, while in the afternoon Dr. Etienne May and Dr. Jean Ollivier (Paris) and Prof. L. Winternitz (Trieste) will speak on the prognosis of hypertension. Other subjects that will be discussed during the meeting include: the acceptance of glycosurics (Sir Walter Langdon-Brown, Prof. Hijmans van den Bergh, and Prof. de Langen); gastro-duodenal ulceration and life assurance (Prof. I. Romanelli, Dr. Faroy, and Dr. Carrié); health service and life assurance (Dr. Samuel B. Scholz, Junr., and Dr. Otto Neustätter). The last session of the congress will be devoted to a varied programme of short papers. The hon. secretary, Dr. Otto May, should be addressed at 142, Holborn Bars, E.C.1.

TWO NEW MEDICAL DIPLOMAS

THE first examinations for the diplomas in child health (D.C.H.) and in anæsthetics (D.A.) recently instituted by the Conjoint Board of the Royal College of Physicians of London and the Royal College of Surgeons of England will be held respectively on Oct. 4th, 1935, and Nov. 8th, 1935. Forms of application for admission may be obtained from the secretary, Examination Hall, 8, Queen-square, London, W.C.1, and must be completed and returned at least 21 days before the examination.

Diploma in Child Health.—The regulations state that the examination (written, oral, and clinical) will comprise the following subjects, special emphasis being laid on their preventive aspects.

(*a*) Anatomy, physiology and pathology of childhood; (*b*) development of the child, physical and mental, including speech, with their disorders; physical education in childhood; (*c*) the hygiene and dietetics of infancy and childhood; (*d*) affections of the newborn; (*e*) disease in infancy and childhood, medical and surgical; (*f*) therapeutics of infancy and childhood, including remedial treatment, physical and mental; (*g*) legislation and public administration in regard to the care of children, including the methods of infant welfare centres and of the school medical service.

The candidate must have been in a recognised children's hospital or department as a resident medical officer for six months or as a clinical assistant for a year, though these conditions may be modified at the discretion of the committee of management in the case of candidates who have carried out original research or whose studies and practice have extended over a long period without fulfilling the exact conditions.

Diploma in Anæsthetics.—The regulations for this diploma are summarised in a leading article (p. 1451). A footnote states that until May 1st, 1938, it shall be open to the Royal Colleges, on the recommendation of the committee of management of the examining board, to grant the diploma, without examination, to an anæsthetist to a general hospital associated with a recognised medical school in the British Empire who has held this appointment for not less than ten years. The fee for such diploma is six guineas, the same as for either of the new diplomas taken by examination.

Appointments

MacDonald, E. K., M.D. Lond., D.P.H., has been appointed Medical Officer of Health, Leicester.

Peirce, G. E. Graves, M.B. Lond., F.R.C.S., Surgical Registrar to the London Lock Female Hospital.

Stringer, W. I. B., M.D. Toronto, Resident Medical Officer to the Royal Northern Hospital.

Trevor, David, M.S. Lond., F.R.C.S. Eng., Hon. First Assistant to the Orthopædic Department of the Charing Cross Hospital.

Woodruff, Keith, M.B. Lond., Hon. Anæsthetist to the Charing Cross Hospital.

Royal National Sanatorium, Bournemouth.—The following appointments are announced:—

- **Smith, S. Watson**, M.D., F.R.C.P. Edin., M.R.C.P. Lond., Physician in Bournemouth;
- **Maxwell, James**, M.D., F.R.C.P. Lond., Physician in London;
- **Adeney, N. F.**, M.B. Camb., F.R.C.S. Eng., Surgeon; and
- **Coles, A. C.**, M.D. Edin., M.R.C.P. Lond., Consulting Physician.

Certifying Surgeons under the Factory and Workshop Acts: Dr. C. P. **Porter** (Kidderminster, Worcestershire); Dr. G. S. **Lawrence** (Bewdley, Worcestershire).

Medical Referee under the Workmen's Compensation Act, 1925: Dr. J. F. **Dick**, of Northwich, for the Altrincham, Warrington, and Northwich County Court Districts (Circuit No. 7).

Vacancies

For further information refer to the advertisement columns

Accrington, Victoria Hospital.—H.S. £150.

Barnsley, Beckett Hospital and Dispensary.—H.P. £200.

Beckenham, Bethlem Hospital, Monks Orchard.—Res. H.P. At rate of £150.

Belfast, Joint Nursing and Midwives' Council.—Examiners.

Birmingham, Monyhull Colony Certified Institution.—Jun. Asst. M.O. £350.

Birmingham, Salterly Grange Sanatorium, near Cheltenham.—Med. Supt. £750.

Birmingham University, Dept. of Industrial Hygiene and Medicine. Research Worker and Lecturer. £600.

Bolton Royal Infirmary.—Hon. Physician for Diseases of the Skin. £100. Also two H.S.'s. Each £125.

Bristol Royal Infirmary.—H.S. to Ear, Nose, and Throat Dept. At rate of £80.

Burton, Devonshire Royal Hospital.—H.P. Also Asst. H.P. At rate of £200 and £150 respectively.

Cambridge, Addenbrooke's Hospital.—Res. Anæsthetist and Emergency O. Also H.S. At rate of £130.

Canterbury, Kent, and Canterbury Hospital.—H.S. At rate of £125.

Central London Throat, Nose, and Ear Hospital, Gray's Inn road. W.C.—Hon. Asst. Anæsthetist. Also Third Res. H.S. At rate of £75.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall.—H.P. At rate of £150.

Chester Royal Infirmary.—H.S. At rate of £150.

Chesterfield and North Derbyshire Royal Hospital.—H.S. to Ear, Nose, and Throat and Eye Depts. At rate of £150.

Children's Hospital, Hampstead, N.W.—Asst. Ear, Nose and Throat Surgeon.

Colchester, Essex County Hospital.—Asst. H.S. £120.

Coventry and Warwickshire Hospital.—H.S. for Aural and Ophth. Depts. At rate of £125.

Derbyshire Hospital for Sick Children.—Res. H.S. At rate of £130.

Doncaster Royal Infirmary.—H.S. to Eye and Ear, Nose, and Throat Depts., Cas. H.S. Also H.S. Each £175.

Dreadnought Hospital, Greenwich, S.E.—H.P. At rate of £110.

Dulwich Hospital, East Dulwich-grove, S.E.—H.P. At rate of £120.

East London Child Guidance Clinic, Upper Woburn-place, W.C.—Hon. Asst. Psychiatrist.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Res. Obstet. Asst. At rate of £50.

Folkestone, Royal. Victoria Hospital.—Sen. and Jun. Res. M.O.'s. At rate of £150 and £120 respectively.

Gateshead Mental Hospital.—Asst. M.O. £500.

Great Yarmouth General Hospital.—H.S. £140.

Harrogate Royal Bath Hospital.—Res. M.O. £156.

Hastings, Royal East Sussex Hospital.—Hon. Asst. Physician.

Hertford County Hospital.—H.P. At rate of £150.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. At rate of £50.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.P. At rate of £100. Also Asst. Physician.

Hull Royal Infirmary.—H.S. to Ophth. Ear, Nose and Throat Depts. At rate of £150.

Ilford Borough Education Committee.—Asst. School Dental Surgeon. £450.

Liverpool, Alder Hey Children's Hospital.—Res. Asst. M.O. £200.

London University.—External Examinerships.

Macclesfield General Infirmary.—Second H.S. At rate of £150.

Maidstone, Kent County Ophthalmic and Aural Hospital.—H.S. to Ear, Nose, and Throat Dept. At rate of £200.

Maidstone, West Kent General Hospital.—H.S. £150.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.

Manchester, Royal Children's Hospital, Pendlebury.—Res. M.O. At rate of £125.

Manchester Royal Infirmary.—Res. Clin. Pathologist. £100.

Manchester and Salford Hospital for Skin Diseases.—H.S. At rate of £100.

Marie Curie Hospital, 2, Fitzjohn's-avenue, N.W.—Res. M.O. At rate of £100.

Market Drayton. Cheshire Joint Sanatorium.—Locum. Six guineas per week.

Mile End Hospital, Bancroft-road, E.—Asst. M.O. £350.

Newport, Isle of Wight County Mental Hospital.—H.P. At rate of 150 guineas.

Paddington Hospital, Harrow-road. W.—Asst. M.O. £350.

Poplar Hospital for Accidents, East India Dock-road, E.—Second Res. O. At rate of £175.

Preston and County of Lancaster Queen Victoria Royal Infirmary. Special H.S. At rate of £150.

Preston, Sharoe Green Hospital.—Sen. and Jun. Res. M.O.'s. At rate of £200 and £100 respectively.

Prison Medical Service.—M.O., Class II. £515 18s.

Queen Mary's Hospital for the East End, E.—Two Cas. and Out-patient Officers. Each at rate of £150.

Rainhill County Mental Hospital.—Asst. M.O., Locum Tenens. 7 guineas per week.

Reading, Royal Berkshire Hospital.—H.S. Also Cas. O. Each at rate of £125.

Rochester, St. Bartholomew's Hospital.—Cas. and Orthopædic H.S. At rate of £175.

Royal Air Force.—Commissions.

Royal College of Surgeons of England.—Examiner in Dental Surgery

Royal Free Hospital, Grays Inn-road, W.C.—Med. Reg. £100.

Royal National Orthopædic Hospital, Great Portland-street, W.—H.S. for Country Branch. At rate of £150.

Royal Naval Medical Service.—Nine M.O.'s.

St. Bartholomew's Hospital Medical College.—Helen Cave Memorial Scholarship. £200.

St. Leonard's-on-Sea Buchanan Hospital.—Hon. Physician.

St. Paul's Hospital for Diseases of the Genito-Urinary Organs and Skin, Endell-street, W.C.—H.S. At rate of £150.

Salford Royal Hospital.—H.S. At rate of £125.

Salisbury General Infirmary.—Res. M.O. £250.

Sheffield Royal Infirmary.—Two H.S.'s. One H.P. Aural H.S. Ophth. H.S. Asst. Cas. O. Each at rate of £80. Also Clin. Asst. to Radiological Depts. £300.

Sheffield University, Dept. of Pharmacology.—Lecturer in Pharmacology. £500.

Shrewsbury, Royal Salop Infirmary.—Two Res. H:S.'s. Each at rate of £160.

South London Hospital for Women, Clapham Common, S.W.—Clin. Asst.

Southampton, Borough General Hospital.—Jun. Res. M.O. £200.

Stafford, Staffordshire General Infirmary.—H.P. and Cas. O. At rate of £150.

Stirling District Mental Hospital, Larbert.—Jun. Assist. M.O. £300.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—Orthopædic H.S.

Swansea General and Eye Hospital.—H.S. At rate of £150.

Tunbridge Wells, New Kent and Sussex Hospital.—Jun. H.S. £150.

Wigan, Royal Albert Infirmary and Dispensary.—H.S. At rate of £150.

Willesden General Hospital, Harlesden-road, N.W.—Hon. Clin. Assts. for Out-Patient Dept. Also Hon. Surgeon.

Winchester, Royal Hampshire County Hospital.—Hon. Surgeon In Ordinary.

Worksop Victoria Hospital.—Sen. H.S. At rate of £150.

The ctories announces vacancies for
ons at Carmarthen (Carmarthen-
Hertfordshire); Ripley (Surrey);

Births, Marriages, and Deaths

BIRTHS

DUKE.—On June 15th, the wife of J. H. Duke, M.B. Belf., Langbourne Mansions, N., of a daughter.

LEAVER.—On June 9th, at Palace-court, W., the wife of R. H. Leaver, M.R.C.S. Eng., of a daughter.

MOONEY.—On June 9th, the wife of A. Craig Mooney, M.B. Liverp., of Plymouth, of a daughter.

SPICER.—On June 2nd, at Kampala, Uganda, the wife of J. R. Spicer, M.B. Lond., Uganda Medical Service, of a daughter.

TOWNSEND.—On June 12th, at Welbeck-street, W., the wife of C. Geoffrey Townsend, M.B. Camb., of a son.

WHITAKER.—On June 14th, in London, the wife of Allen Whitaker, M.B. Lond., Guildford, of a daughter.

MARRIAGES

DINGWALL—WOODHAM.—On June 8th, at St. Nicholas Church,
Cranleigh, Surg. Lt. Ronald Aberd.,
R.N., to Elizabeth Woodham te Capt.
Charles Burnett Woodham, rnwall's
Light Infantry, and of Mrs. Surrey.

HARDY—WATSON.—On June 15t Church,
Thomas T. Hardy, B.M., B.Ch. Oxon., son of Dr. and Mrs. T. M. Hardy, West Byfleet, Surrey, to Mollie Ursula, youngest daughter of Mr. and Mrs. Gerald P. Watson, Pynford, Surrey.

MCCRAE—FRANKLING.—On June 15th, at St. John de Sepulchre, Norwich, Dr. Ian Bruce McCrae, of Johannesburg, to Muriel Burton Frankling, of Norwich.

WARD—KERSHAW.—At St. Mary's Church, Knighton, Leicester, on June 14th, by the Rev. Canon Matthews, Dr. Gerald Ward, M.A., M.B. Cantab., younger son of Mr. and Mrs. Ernest Ward of Knighton Rise, Leicester, to Marjorie, only daughter of Mr. and Mrs. C. R. Kershaw, of Knighton-road, Leicester.

DEATHS

DOUGLAS.—On June 12th, at Harold-road, Norwood, S.E., John J. Douglas, M.D., F.R.C.P. Edin., D.P.H., aged 69.

FULLER.—On June 14th, Courtenay James Fuller, M.R.C.S. Eng., of Plumstead, S.E., aged 75 years.

MACKENZIE.—On June 13th, at Ryde, I.W., Kenneth Walter Ingleby Mackenzie, M.R.C.S. Eng.

THOMPSTONE.—On June 12th, suddenly, at St. Saviour, Jersey, Sydney Wilson Thompstone, C.M.G., F.R.C.S. and P. Edin., late P.M.O., Northern Nigeria.

TROUT.—Joseph Henry Ensor, L.R.C.S., L.R.C.P., aged 71, at "Lullington," Edgbaston, Birmingham, on June 14th.

WILSON.—On June 14th, at a London nursing-home, James Wilson, M.D. Aberd., of Stonehill-road, East Sheen, S.W., and late of Goldhawk-road, Shepherds Bush.

WRIGHT.—On June 10th, at Hoveton St. John, near Norwich, Bernard Duncan Zorapore Wright, M.R.C.S. Eng., aged 72.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

WORCESTER ROYAL INFIRMARY.—The death-watch beetle has caused havoc in the wood-work of the older buildings at this hospital, and the cost of renovating the floors and ceilings will be £11,000. Last year there was an excess of expenditure over income of £2847 compared with over £3000 in 1933. The income from the contributory scheme has again increased and the total number of contributors in city and county is estimated at 30,000.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
TUESDAY, June 25th.
Pathology. 8.15 P.M. for 8.30 P.M. Summer Meeting at the Wellcome Museum of Medical Science, 183, Euston-road, N.W. (Dr. S. H. Daukes.)
SATURDAY.
Disease in Children. Meeting in Cardiff by invitation of Dr. A. G. Watkins.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.
THURSDAY, June 27th.—6.30 P.M. (Adolph Tuck Hall, Woburn House, Upper Woburn-place, W.C.), Annual General Meeting. 7.30 P.M., Dinner. 8.30 P.M., Mr. Dan Frankel: The Future of the Municipal Medical Service.

MEDICO-LEGAL SOCIETY.
THURSDAY, June 27th.—8.15 P.M. (11. Chandos-street, W.), Annual General Meeting. Mr. Everard Dickson and Dr. Gerald Slot: Questions of Drunkenness in the Courts.

BRITISH PSYCHOLOGICAL SOCIETY.
Medical Section.
WEDNESDAY, June 26th.—8.30 P.M. (36, Gloucester-place, W.), Dr. W. Clifford M. Scott: Some Apparent Disturbances of Reality due of Ideas of Omnipotence—with special reference to Disturbed Ideas about Time.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.
WEDNESDAY, June 26th.—5.30 P.M. (1, Wimpole-street, W.), Lord Horder: Pruritus. (Prosser White oration.)

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.
THURSDAY, June 27th–29th.—Annual Conference at Southport.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Thornhaugh-street, W.C.
Fever Hospital Medical Services Group.
FRIDAY, June 28th.—4.30 P.M., Dr. G. Ronaldson: Observations on the Pathogenesis of Diphtherial Paralysis.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, June 24th, to SATURDAY, June 29th.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N.
All-day course in medicine,
—NATIONAL HOSPITAL FOR
Westmoreland-street, W.1.
(Open to all.)—Courses and clinics arranged by the Fellowship are open only to members and associates.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, June 27th.—2 P.M., Mr. Denis Browne: Talipes. 3 P.M., Dr. W. W. Payne: Nephritis from the Laboratory Aspect.
Out-patient clinics daily at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

CENTRAL LONDON, THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.
MONDAY, June 24th, to FRIDAY.—4.30 P.M., Course in Methods of Examination and Diagnosis.

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.
THURSDAY, June 27th.—3 P.M., Dr. W. G. Wyllie: Demonstration.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W.
MONDAY, June 24th, to FRIDAY.—First week of Intensive Course.

INSTITUTE OF CHILD PSYCHOLOGY.
WEDNESDAY, June 26th.—6.15 P.M. (Friends House, Euston-road, N.W.), Dr. Ethel Dukes: Phases of Development. 8.15 P.M., Dr. Margaret Lowenfeld: Comedy and Tragedy in Play.

INSTITUTE OF MEDICAL PSYCHOLOGY, Malet-place, W.C.
WEDNESDAY, June 26th.—3 P.M., Dr. H. Crichton-Miller: Summary. 4.30 P.M., Dr. Cedric Shaw: Summary.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.
WEDNESDAY, June 26th.—3 P.M., Visit to Buckston Browne Research Farm, Downe, Kent. (Sir Arthur Keith and Mr. Laurence O'Shaughnessy).

UNIVERSITY OF BIRMINGHAM.
TUESDAY, June 25th.—3.30 P.M. (General Hospital), Mr. Beatson Hird: Demonstration of Ophthalmic Cases.
FRIDAY.—3.30 P.M. (Children's Hospital), Dr. J. M. Smellie: Demonstration of Cases.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE.
SUNDAY, June 23rd.—10.30 A.M. (Newcastle General Hospital) Mr. D. R. MacGregor: Clinical Demonstration.

NOTES, COMMENTS, AND ABSTRACTS

THOMAS BENTLEY

PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS

BY R. R. JAMES

MUNK thought that Thomas Bentley must have died between the years 1531 and 1541, because his death is not recorded in the college annals and the records for those ten years are defective. He notes the fact that he was thrice president of the College and that his name is not in the list of elects for 1541, but he omits to state that Bentley was physician to Henry VIII. and to Edward VI.

I am in a position to supplement Munk's brief account of Bentley. It is almost certain that he was a member of a Warwickshire family branches of which owned property at Kineton and Stratford upon Avon; but he was probably a son of Geoffrey Bentley, of Woodstock, and was born c. 1485. After taking his M.D. Oxon., in 1518, he was physician to the Duke of Buckingham. The latter was executed in 1521, but his physician does not appear to have been accused of participation in the high treason for which Buckingham suffered.

He was at Oxford at the time, for I find that on April 20th, 1521, he received an acquittance for property given to the University of Oxford by John Thorne, late Abbot of Reading. He was for a time Fellow of New College. His wife's surname is unknown, but her christian name was Anne. While in Oxford they lived in one of the George Halls, possibly in St. Mary's parish. In the same year (1521) Dr. Bentley, physician of Oxford, was sent for to Court. On the death of Linacre, in 1524, Bentley was appointed physician to Henry VIII. He resided in St. Botolph Without in "Alrichgate" (Aldersgate). In 1528 he was the recipient of a New Year's gift from the King. Previously, in 1525, the Canons of Holy Trinity let the demesne lands of the rectorial manor of Tottenham, with the great tithes, to Bentley for 40 years. Lee, Archbishop of York, in 1533, recommended him for the manor of Stockwell, saying that "he is an old friend of mine and a right honest man." At about this time he was unfortunate in having his house burgled by a woman named Margaret Maxeborne; and the odd thing is that the lady in question received a Royal pardon, dated at Greenwich, in May, 1533.

Bentley received a salary of £10 a quarter from 1528 to 1547 and his servant had a New Year's gift from the King in 1538 and 1540. On Jan. 10th, 1544–45 he let his property in Oxford, by charter, to Harman Evans, bookseller. It must have been at about this time that Bentley retired to Stratford upon Avon, for he certainly added to his property there in 1546. He rented, from Squire Clopton, the Great House for 40 years. This house was later known as New Place and was the residence of William Shakespeare.

Bentley died, probably early in 1549 and was buried in the church at Stratford upon Avon. The following is an abstract of his will.

(P.C.C. Cood, 6). 26 Jan., 1548. Thomas Bentley, of Stratford upon Avon, Co. Warwick. Dr. of Physick to the late King Henry VIII. Soul to God. Body in the parisshe churche of Stratford. To wyfe Anne my best standinge cuppe of sylver and gylte wt the couer, a neste of goblettes of syluer & gylte wt the couer, my beste salte wt his couer, syx pottes of syluer & gylte wt their couers and all my syluer spones, wt all my fuelles and all my right tytle and interest and terme of yeres that I have of and in my house in Oxford called George Hall together wt the indenture of the same house wt certeyn ymplementes therein remaynynge as Standerth, whiche house is now in the tenure of Harman Evans. Item I bequeath to my sonne William Bentley my seconde beste standynge cuppe of syluer and gylte wt the couer and a potte of syluer and gylte wt the couer. I bequeath to Anne Bentley my daughter my seconde beste syluer salte wt his couer, thre pottes of syluer and gylte wt their couers and a kowe orelles XXs. in money. To my daughter Dorothe Bentley my thirde salte of syluer and gylte wt his couer, a kowe and a calfe orelles XXs. in money. To Robert Wyncocke a syluer cuppe wt the couer. To William Clerke, whome I have brought upp of charitie, twoo heyfers when married. Residue to wife Anne, my sole executrix. Friends Thos. Blount[1] and Robt. Wyncocke, supervisors. The said Thomas to have a syluer potte for his pains. Wit. John Jeffries, Thos. Waturman, Laurence Seyton, Wm. Myns. Proved at London, 4 March, 1549.

Bentley's widow is said to have married a certain Richard Charnock. His son William married Anne Porter and died in Shropshire in 1547. Of his daughters, Anne married William Botterell,[2] of Aston Botterell, Salop, after her father's death. Dorothy was married, after her father's death to Roger Gifford, of Hillesden, Bucks; while Barbara, who is not mentioned in the will, married Thomas Raynsford, of Little Compton, Glos.

I am indebted to Mr. Harvey Bloom for the transcript of the will and to Mr. Frederick Wellstood, F.R.Hist.Soc., Librarian of Shakespeare's Birthplace for the loan of a privately printed brochure from which most of the above facts are abstracted.

The monotonous repetition of silver salts, cups, &c., with covers shows that Bentley must have made good the depredations of the burglar.

FOOTNOTES

[1] Thomas Blount may be a scion of the ancient Shropshire family of Blount, of Kinlet and Mawley Hall, though his exact relationship to Sir George Blount, whose monument in Kinlet Church is one of the finest Elizabethan monuments in the country, is not clear to me. He was possibly Thomas Blount, of Kidderminster, grandson of Sir John Blount, of Kinlet, who died in 1524. If so he was a cousin of Sir George.

[2] The Botterell family at Aston date from A.D. 1200. I know the place well as I was born and bred in the next parish a mile away. Like Hardy's D'Urbervilles the family fell on evil times and I think I am correct in stating that the last direct descendant died in very reduced circumstances about the middle of last century.

RADIOGRAMS WHILE YOU WAIT

WHEN a patient is referred to the X ray department much time is always wasted before films and reports are available. Most of this delay comes from the slow drying of films, and unless wet films are sent round the hospital—which means that they are often spoilt—the clinician is seldom able to see a radiogram of his patient until a later session. Dr. A. E. Barclay has tried to devise means of expediting the production of a dry film, and we have already given some account of observations communicated by him to the British Institute of Radiology last February. Those interested may now study his paper at leisure in the June issue of the *British Journal of Radiology*.

An X ray film has to be developed, fixed, washed, and dried. The first two of these processes take about five minutes each and cannot be speeded up, but Dr. Barclay shows that washing can certainly be accelerated. Provided that the washing tanks are small and the water is running fast and is not polluted by the introduction of more films from the fixing tank, a film can be perfectly washed and chemically pure in from three to five minutes. In the drying process two factors apparently play a part—namely, heat and draught. Although the gelatine on the films melts in solutions that reach a little over 100° F., it is found that a film can be dried in air at a temperature of 160° F., or even higher, if a strong draught is maintained. The explanation lies in the cooling caused by intense surface evaporation. With rapid drying there must, however, be no drops of water left on the surface—i.e., the moisture distribution must be even—or the unequal drying will give rise to water marks. To avoid this, Dr. Barclay puts the films through an ordinary household wringing machine with rubber rollers. Even with the maximum pressure obtainable, he says, no damage was done to the radiogram, and by using the wringer before drying some 30 to 40 per cent. by weight of the moisture could be eliminated. Under experimental conditions, he reports, films have been completely processed, with satisfactory washing and drying, within 15 minutes.

The need for a more rapid radiographic service is urgent, especially in the larger hospitals where patients are drawn from a wide area and cannot afford double travelling expenses—to say nothing of the waste of time of the clinician who has to review the case on the second visit. Even if an effective rapid drying machine were expensive, it might quickly pay for its cost if it enabled the clinician to deal effectively and finally with patients during one session. Apart from the possibility of damage, there is a psychological objection to the examination of wet films faute de mieux. The approach of the radiologist or the clinician to a wet, unfinished film tends to be casual, and he is less likely to examine it with the care for every detail which is a necessary part of routine.

SNAKE VENOM AS AN ANALGESIC

In a recent leading article we referred in passing to the use of snake venom in the relief of pain, and it is appropriate to recall a small series of cases of inoperable carcinoma thus treated which was described not long ago by H. R. Calderón (Semana méd., 1934, xli., 1109). Venom was first employed for this purpose, he says, by Monaelesser in 1930. In the present series the venom of the snake *Lachesis alternatus* was used because of its comparatively low content of hæmotoxin. Before any patients were treated the minimal toxic dose was worked out on rats, and the human dosage was calculated as one-tenth of the toxic dose. In rats the minimum toxic dose was found to be 0·375 mg. per kg., so that the dose administered to the patients was 0·0375 mg. per kg. The venom was administered either subcutaneously or intravenously. None of the 8 patients failed to obtain relief when it was given intravenously, but in 2 of them subcutaneous injections were ineffective. Calderón concludes that the venom is less potent, but also less hæmotoxic, than cobra venom, the period of analgesia lasting from 3 to 18 hours, which is considerably less, he thinks, than the period of relief given by cobra venom. Neither in the patients nor in rats inoculated with malignant tumours were any regressive changes detected in the growth.

In some respects this agrees with the experience of Jacques Lavedan, who has for some two years given injections of cobra venom to patients suffering from various forms of malignant disease (Bull. de l'Acad. de Méd., 1935, No. 5, p. 195). In 51 cases the treatment was continued systematically for at least four months, the cobra venom being introduced either directly into the new growth or at some distance from it, and, broadly speaking, nothing but failure was registered. It is true that considerable relief from pain ensued in some cases, but it could have been obtained more reliably and cheaply with morphia. Histological examination of the tumours supplied no reliable evidence that their vitality had been injured.

SUMMER TOURS

The Le Play Society organises holiday courses on which various aspects of the same region are considered and field studies from the point of view of archæology, art, architecture, geography, geology and botany, and sociology are made. The material collected on these tours is afterwards used for the publications of the society. The programme for this year includes a tour to Bulgaria for an economic and social survey, and a visit to the Caucasus. Other groups will go to Denmark and Sweden, where housing and social problems will be the special subject, and to Andorra, where it is planned to make an economic and geographical survey. At home, several centres have been chosen for work of differing types: a training course in survey methods will be held at Cranham in the Cotswolds, and survey of the Island of Lewis is being arranged for August. Full details can be obtained from Miss M. Tatton, the director of the society, at 58, Gordon-square, London, W.C. 1.

A NOTEBOOK FOR TRAVELLERS

The publishers of Twentieth Century Health and Pleasure Resorts have brought out a little book, 6½ by 4½ inches, condensing the information contained in the larger volume, along with hints to travellers, diagrams of routes, and a few essential details of European countries, how and where to travel in them, what to see and where to stay. At the end is a list of cure resorts, mountain homes and home schools for delicate children, sanatoria, bath resorts classified under the complaints for which they are usually recommended, schools and educational homes. The result is a booklet which can be carried in the pocket and cannot fail to be of assistance in some way to every class of traveller. The notes on why we travel, how to travel intelligently, what to do and not to do on the continent, contain a philosophy of travel from which even experienced travellers might benefit. It contains the names of nearly 2000 hotels, pensions, and other establishments and can be obtained price 1s. through Messageries Hachette or from the Anglo-Continental and International Publishing Offices, Lausanne—British agency at Warwick Chambers, Corporation-street, Birmingham.

NEW PREPARATIONS

Oleochrysine Lumière.—The Anglo-French Drug Co., Ltd. (11 and 12, Guilford-street, London, W.C.1), is placing on the market a new preparation entitled Oleochrysine Lumière, a product of the Lumière Laboratories at Lyons. The drug represents a departure in gold therapy; the new organic gold salt (calcium auro-thioglyceryl sulphonate) contains 35 per cent. gold and 4·53 per cent. calcium, is soluble in water but is supplied for therapeutic use as an oily suspension whereby its activity is prolonged. The therapeutic indications for the use of gold are known to be numerous, various pulmonary conditions improving under its absorption, while some of the symptoms of chronic rheumatism and certain skin diseases are benefited by its exhibition. The Lumière Laboratories, in enumerating the conditions for which oleochrysine may be found useful, point to the calcium content as increasing the tolerance to gold, the risk of unfortunate reactions being reduced to a minimum.

Messrs. Burroughs Wellcome and Co. announce that all "Wellcome" Brand Insulin is now made with pure crystalline insulin. It is claimed that this is the first commercial product to be so prepared.

The Denver Chemical Manufacturing Company has removed to Carlisle-road, London, N.W.9, and requests that all communications should now be sent to the new address.

Cottage Hospital Scheme.—Iver, Denham, and Langley Cottage Hospital hopes to build a new hospital in Widecroft Meadow, Iver, at a cost of over £10,000, and the site has been offered for the modest sum of £150. A new hospital is necessary, for during the last ten years out-patients' attendances have increased from 540 to 1836.

Corrigendum.—*Miss* M. Forrester Brown, M.S., was the author of the article on p. 1377 of our last issue.

ADDRESSES AND ORIGINAL ARTICLES

THE UNHAPPY COLON *

By Arthur F. Hurst, D.M. Oxon., F.R.C.P. Lond.
SENIOR PHYSICIAN TO GUY'S HOSPITAL, LONDON

No organ of the body is so misunderstood, so slandered, and so maltreated as the colon. Text-books of anatomy are apt to describe it as it is found in the dissecting-room, not as it occurs in a living man. Text-books of physiology describe its motor functions as seen under experimental conditions in animals, and rarely pay sufficient attention to the results of observations made on healthy human beings, and they ignore more or less completely its secretory functions. The colon is slandered every day in the advertising columns of the popular press, which accuse it of sins it never commits, and the mass suggestion which results from constantly reading about the disastrous effects of intestinal intoxication results in most of the lay public and many of the medical profession joining in these slanders. By promoting the sale of purgatives and encouraging the use of various other methods of irritating the colon, these slanders result in maltreatment. No wonder that the colon is unhappy.

Motor Functions of the Colon

Walter Cannon, the distinguished professor of physiology at Harvard, whilst still a medical student in 1897, conceived the idea of watching cats with the recently discovered X rays after they had been fed on a mixture of food and opaque bismuth salts. He found that when the small intestines were thus visualised, two types of motor activity could be recognised. The first is peristalsis, by means of which the contents are propelled onwards. The second is segmentation, by means of which the bowel is divided into short segments by localised contractions of the circular muscle-fibres; relaxation quickly follows and is accompanied by contraction in the centre of the original segments, with the result that the food is thoroughly mixed with the digestive juices and the chyme is brought into intimate contact with the mucous membrane, which can then absorb the soluble products of digestion.

Under normal conditions the ileo-cæcal sphincter is closed, so that the chyme which travels rapidly down the small intestines remains for a considerable period in the last few inches of the ileum, which constitute a kind of "intestinal stomach," in which pancreatic and intestinal digestion is completed and the greater part of the products of digestion are absorbed. When the next meal is taken a gastro-ileo-cæcal reflex occurs, which results in the segmentation in the terminal ileum being replaced by peristalsis. The ileo-cæcal sphincter relaxes as each wave of peristalsis reaches it, so that the cæcum and ascending colon become filled, whilst the "ileal stomach" is emptied in preparation for the arrival of more chyme derived from the meal which has just been consumed.

When the colon is watched with the X rays no movements can be recognised under ordinary conditions, and for a long time it remained a mystery how its contents ever reached the rectum. In 1907[1] we made hourly tracings of the colon in normal individuals who had taken an opaque meal the previous day. We found that no change occurred except during the hours in which a meal had been consumed (Fig. 1). This led us to watch the colon during and immediately after meals.[2] We then discovered that a gastro-colic reflex occurs when food entered the stomach, which results in "mass peristalsis" of the colon (Fig. 2), a movement which had been independently observed by Holzknecht and by Barclay. The contents of the colon are conveyed by one or two powerful waves of contraction from the ascending colon to the pelvic colon. The ascending colon is thus emptied in order to allow the entry of the contents of the ileal stomach, whilst the fæces are stored in the pelvic colon. The fæces do not pass beyond the pelvi-rectal flexure, the acute angle at the junction of the freely movable pelvic colon with the fixed rectum, owing to the presence of an obstacle in the form of a prominent fold of mucous membrane, the uppermost valve of Houston. The pelvic colon gradually fills from below upwards, whilst the rectum remains completely empty.

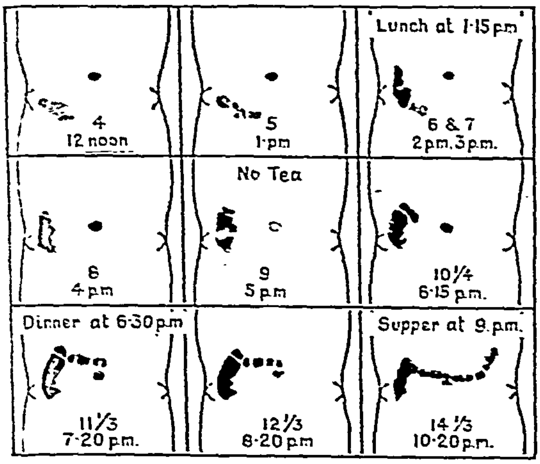


FIG. 1.—Hourly tracings to show effect of meals on the movements of the colon. The opaque meal was taken at 8 A.M.

By taking radiograms at intervals of a minute or of three minutes, Dr. P. J. Briggs and I have found that the familiar haustrated appearance of the colon seen with the X rays is continually changing (Fig. 3); the "haustrations" do not correspond, as was formerly believed, with the antomical haustrations seen in the colon after death, which depend upon the tonic contraction of the muscular coats, but represent phases in the constant movements of the mucous membrane which are produced by the muscularis mucosæ, as first suggested by Forssel of Stockholm. These movements have the same effect as the segmentation of the small intestines, and by constantly bringing successive portions of the soft fæces into contact with the mucous membrane they promote absorption of water and the gradual conversion of the fæces into the form in which they are eventually passed.

An infant is trained to open his bowels when he is put on a chamber, no mental process being concerned in the act. In the course of time an elaborate conditioned reflex develops, in which getting up, a bath, dressing, breakfast, and finally sitting down with a newspaper and a pipe in the familiar w.c. take part, as a result of which the biggest wave of mass peristalsis of the day occurs, the whole of the colon

---

* An address given at the Massachusetts General Hospital, Harvard University.

taking part (Fig. 4, *a*, *b*, and *c*). By introducing a balloon through a sigmoidoscope we found that distension of the pelvic colon produced discomfort in the lower part of the abdomen, but distension of the rectum produced a perineal sensation, which is indistinguishable from the normal "call to defæcate."[3] When the fæces which have collected in the pelvic colon during the previous 24 hours enter the rectum as a result of the conditioned reflex I have just described, they give rise to the call to defæcation. The diaphragm and abdominal wall are then voluntarily contracted; the rise in pressure within the rectum calls forth the final reflex, which results in the contraction of the rectum as a whole with relaxation of the anal sphincter through which the fæces are evacuated.

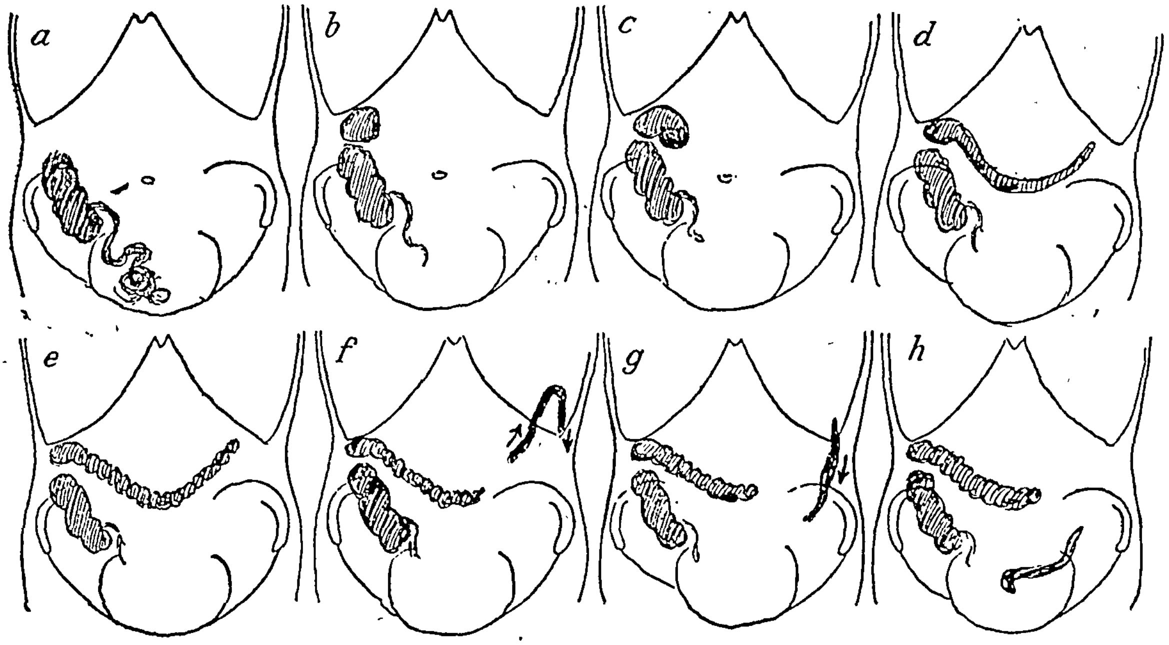

FIG. 2.—Tracings showing mass peristalsis occurring immediately after luncheon at 12 noon, an opaque meal having been taken at 7 A.M. An interval of five minutes occurred between the series (*a*) to (*c*) and the series (*c*) to (*h*).

Constipation

Many years ago I suggested that all cases of constipation could be divided into two groups, those in which the passage along the colon is abnormally slow—colonic constipation—and those in which the rectum is reached without delay but defæcation is inefficient—a group to which I gave the name of dyschezia. I am now inclined to believe that all cases of constipation are due to dyschezia, the delay in the colon in the first group being a result of inefficiency of the conditioned reflex, which should result every morning in the partial evacuation of the proximal part of the colon into the pelvic colon and of the pelvic colon into the rectum, though doubtless in some cases the gastro-colic reflex which should help to empty the proximal colon after each meal is also deficient. In the more obvious cases of dyschezia the first part of the reflex is unimpaired, but owing to slackness and other causes it is *not followed* by the second part, in which the rectum contracts and the anal sphincter relaxes, so that the rectum is found to be packed with fæces at whatever hour it is examined.

The majority of cases of constipation can be cured by re-establishing the conditioned reflex upon which successful defæcation depends. Simple explanation of the physiology of defæcation and encouragement are often all that is required, but it may be necessary to reduce the work the muscles of defæcation have to perform by giving paraffin or some unirritating vegetable mucilage, such as agar agar, isogel, or coreine, which increase the bulk and soften the fæces, together with a diet containing plenty of fruit and green vegetables.

The vast army of hypochondriacs, who are never happy unless their stools conform to an ideal which they have invented for themselves, can only be cured by making them realise that fæces have no standard size, shape, consistence, or colour; they are then ready to follow the example of the dog rather than that of the cat—and never look behind them.

Purgatives

It is sad that the description given by Gulliver to the Houyhnhnms of the habits of his fellow countrymen is as true to-day as it was in 1727: "they take in at the orifice above a medicine, equally annoying and disgustful to the bowels, which relaxing the belly drives down all before it; and this they call a purge." Over £10,000,000 are spent annually in Great Britain on patent medicines, the majority of which are purgatives. When a habitual pill-taker is cross-examined and his intestinal functions are investigated, it is found in the majority of cases that he is not constipated at all. He takes purgatives for symptoms which newspaper advertisements tell him are caused by "auto-intoxication," the result of sluggishness of the bowels. But when he is persuaded to leave his bowels alone, his symptoms generally disappear at once, as they are a sequel of the toxæmia caused by the artificial diarrhœa produced by purgatives and not of constipation, which may cause local discomfort and is often a source of much anxiety to the patient, but very rarely gives rise to toxæmia, as hard dry fæces do not undergo bacterial decomposition, and, even if they did, it would be impossible for the mucous membrane to absorb anything from them. An aperient upsets the delicate mechanism of the ileo-cæcal sphincter, which normally allows for the complete digestion of food in the almost sterile small intestine, in which the products are absorbed without undergoing bacterial decomposition. When an aperient is taken a good deal of semi-digested food reaches the colon, which is swarming with bacteria, which flourish when the contents of the colon are fluid instead of semi-solid or solid as they are under natural conditions. Putrefaction of proteins, fermentation of carbohydrates and bacterial decomposition of fats occur, and the toxic products are absorbed. The liver is often able to render them inert and the kidneys to excrete what has escaped from the liver, but if either of these organs is inefficient or if the drugging continues over long periods, toxic symptoms occur.

Enemas

According to Pliny the ancient Egyptians learnt how to wash out their bowels by observing the habits of the ibis: "he washes the inside of his body by introducing water with his beak into the channel by which our health demands that the residue of our food should leave." It is a pity to deprive the ibis of his claim to this epoch-making discovery, but when he appears to be giving himself a Plombières douche, what he really does is to wash his beak in water and then oil it on his preen-gland, which is situated near the anus, in preparation for preening his feathers.

In the seventeenth century enemas became extremely popular in France. Molière in the "Malade imaginaire," speaks of "un petit clystère insinuatif, préparatif et rémollient pour amollir, humecter, et refraîcher les entrailles de Monsieur," and Voltaire, writing to a young friend in 1754, says that one of the essential gifts he should look for in a wife is the ability to administer an enema rapidly and pleasantly. Louis XI. believed so much in the efficacy of the treatment that he had a daily enema administered to his dogs with a syringe of copper, and the pious Duchess of Alba tried as a last resort the effect of enemas containing a suspension of powdered religious relics for her dying son, but unfortunately without effect.

Enemas were introduced into England early in the nineteenth century, but the literal translation of "lavement" led to the addition of soap, which is still used extensively here though nowhere else—an unfortunate mistake, as soap solution is extremely irritating.

About 25 years ago it gradually became realised that intestinal lavage as practised in Plombières and other spas in France and England caused more colitis than it ever cured, but the last five years have seen a revival of the treatment in England in a more pernicious form than ever, in which the patient has his colon washed out continuously for a couple of hours with as much as 30 pints of fluid. There are now in London several "colon laundries," as they are called in America, in which this unpleasant and unscientific treatment is practised, and when the course is completed the patient is often persuaded to buy an apparatus in order to continue the good work at home.

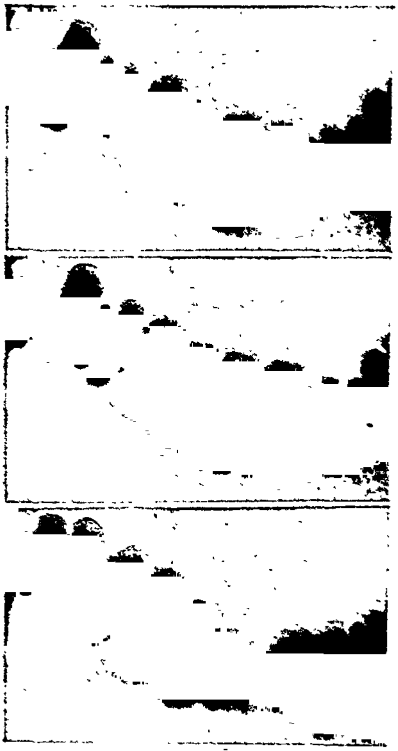

FIG. 3.—Three radiograms taken at intervals of one minute showing changes in outline of colon resulting from segmentation. (Dr. P. J. Briggs.)

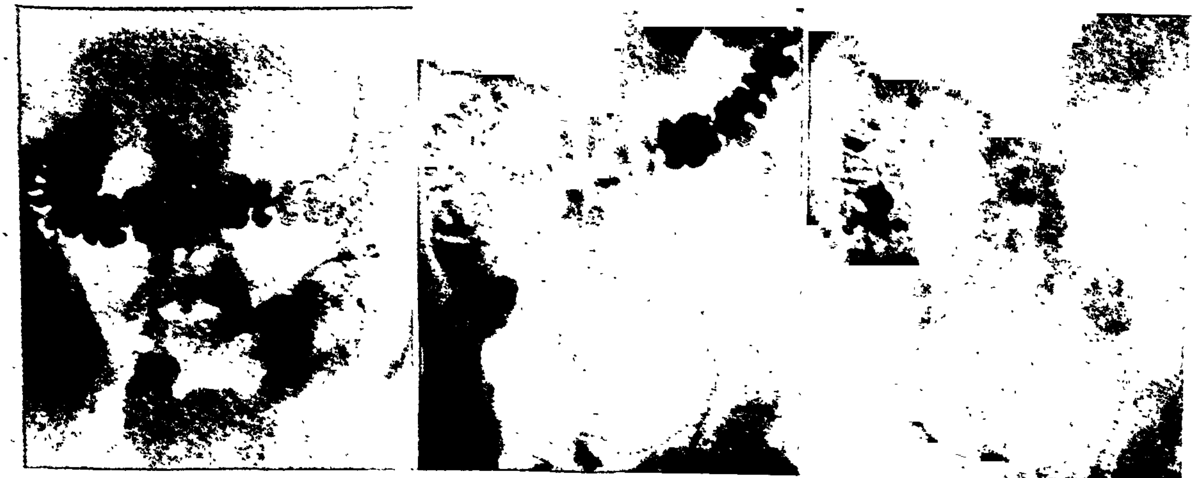
A man of 50 had acquired the habit of washing himself out for two hours every morning and again every evening on his return from business. It was difficult to remove his obsession that a "clean" colon was essential for health, but a week's experience with no lavage and no



(a) (b) (c)

FIG. 4.—Radiograms showing results of defæcation in a normal man: (a) 9.15 A.M., before defæcation—barium was taken previous evening; (b) 9.25 A.M., after first defæcation; (c) 11.20 A.M., after second defæcation. (Dr. P. J. Briggs.)

medicine led to such an improvement in his health that he has continued ever since to let his bowels work naturally.

Intestinal lavage is required as an exceptional measure in exceptional cases, but nothing but harm can result from its present indiscriminate use. Plain water or normal saline solution should be employed, and no irritants such as soap, turpentine, and antiseptics should be added.

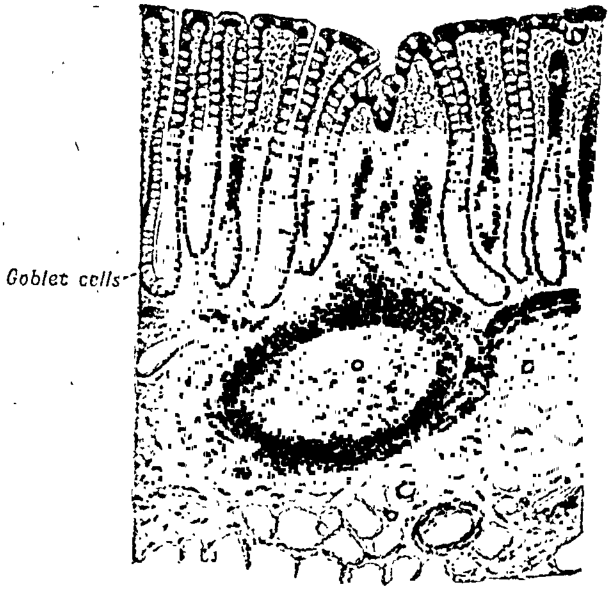


FIG. 5.—Mucous membrane of the human colon showing numerous goblet cells in the crypts of Lieberkühn. × 70: (after Braus). (Reproduced from the *Proceedings* of the Royal Society of Medicine, 1934, xxvii., 678.)

Size, Position, and Mobility of the Colon

Many years ago Barclay showed that the tone of the stomach varied with the volume of its contents, and the same is true for the colon. If it were not for this the internal pressure would rise with each increase in the bulk of the contents, and as the sole adequate stimulus of visceral discomfort and pain in a hollow organ is increased tension in its muscular coat, discomfort and pain would frequently occur, whereas the normal process of digestion takes place without giving rise to any sensation. Both the transverse and longitudinal muscle coats are involved in this adaptation. Consequently, the transverse diameter and the length of the cæcum and ascending colon are less during the few hours after complete defæcation following breakfast than during the rest of the 24 hours (cf. Fig. 4, *a*, *b*, and *c*). The transverse colon may vary in length by as much as 2 in. according to whether it is full or empty, and the iliac colon, which is generally empty, can often be felt as a contracted and almost solid cord. A knowledge of these variations would prevent the possibility of such erroneous diagnoses as dilated atonic cæcum and spasm of the iliac colon being made as a result of palpation and X ray examination, and constipation would not be regarded as a result of an atonic large intestine.

The position of the colon varies greatly in different individuals. It also varies greatly in the same individual with changes of posture, as Barclay has so well demonstrated, and according to whether the stomach and bladder are full or empty. Radiologists still diagnose a pelvic cæcum and ptosis of the colon far too frequently, and surgeons have not yet discarded operations for fixing the colon in the position it occupies in the illustrations of text-books of anatomy but nowhere else, not having realised that the healthy bowel requires "absolute freedom of movement and an entire absence of fixed points" (Barclay). In the erect position the cæcum of healthy persons is as often in the pelvis as in the right iliac fossa, and even when it makes a permanent home of the pelvis it can be very warm and comfortable there. In many instances it is far better there than higher up, because it is associated with an ascending colon which is longer than the average, so that it would be cramped and kinked if it were in the right iliac fossa. Some surgeons are difficult to please. If the colon is fixed by adhesions they mobilise it, if it is unduly movable they fix it.

A woman of 26 had her appendix removed for abdominal pain when she was 17. As the symptoms persisted she was operated upon again two years later and adhesions were divided. When she was 23 another surgeon operated because, as he wrote to me, "I thought there were adhesions pressing over the colon." He found, however, that there were no adhesions, the bowel being "abnormally movable," so he fixed it—thus doing exactly what he intended to undo when he advised operation. After this the symptoms were worse than ever, but they disappeared when the patient was persuaded to give up aperients, which she had throughout been taking in excess.

Secretion of Mucus

The mucous membrane of the colon, like every other mucous membrane, secretes mucus in response to irritation. The majority of the cells lining the crypts of Lieberkühn are goblet cells (Fig. 5), and their ability to secrete mucus in response to mechanical and chemical irritation is a sign of their healthy activity. The fæces which collect in the pelvic colon are often dry and hard. Mucus is secreted, so that the scybala are covered with a thin layer of mucus, which facilitates their smooth passage through the rectum and the narrow anal canal. When a purgative is taken the mucous membrane secretes mucus in order to protect itself from damage, as the drug acts by irritating the mucous membrane and so initiating a local reflex leading to increased motor activity. Consequently the loose stool which is passed often contains excess of mucus. Enemas of all kinds, but especially those containing irritants such as soap, turpentine, potassium permanganate, and silver preparations, also act as irritants and cause increased secretion of mucus.

Patients frequently bring illuminating reports from the attendants at colon laundries. The following is typical.

A boy of 18 had always had a tendency to constipation and had been continually dosed by his mother with aperients. His report stated that he had been given an irrigation of 30 pints, the treatment lasting one hour and ten minutes. "The first 12 pints brought away loose fæces but no mucus, but after that a large quantity of jelly mucus was passed continuously until the end of the treatment." That is to say, 12 pints of fluid were required to irritate the healthy mucous membrane of this boy sufficiently to produce excess of mucus, but when once it began to be secreted it naturally continued, and there would still have been mucus present if he had received 100 instead of 30 pints.

The patient is often told that the mucus has been accumulating in his colon for weeks or months and that is why he has never seen it in his stools, whereas the truth is that his mucous membrane is none the worse for a few pints of water, but after the first few pints it has to protect itself by secreting mucus. It is sometimes reported that by the end of the patient's "cure" little or no mucus is present, the explanation being that the patient's mucous membrane responds at first by the secretion of mucus to the unaccustomed irritation, but after some weeks the mucus-secreting cells become exhausted and go on strike.

The mucus present under these circumstances contains epithelial debris and bacteria, but no leucocytes or red corpuscles. Florey has shown that the sticky mucus secreted by the goblet cells picks up minute particles from the surface of the mucous membrane. It is then rolled into small masses by the activity of the muscularis mucosæ and expelled with the fæces. Consequently the mucus contains the epithelial debris, which is constantly being shed by the mucous membrane, and the bacteria which normally inhabit the colon, but their presence, unlike that of leucocytes, red corpuscles, or pathogenic organisms, is not an indication of inflammation or infection. The sigmoidoscope also shows that the mucous membrane is perfectly healthy. Yet the discovery of mucus in the stool is widely regarded as evidence that "mucous colitis" is present, and mucous colitis is consequently believed to be a very common disease, whereas the presence of mucus with a formed stool, with an unformed stool when a aperient has been taken, or in the result of a colon "wash-out," is really evidence that the mucous membrane is healthy and capable of protecting itself from damage by mechanical and chemical irritants.

When excess of undigested food reaches the colon, as in achlorhydric gastritis and in enteritis, the colonic mucous membrane may respond to the irritation by secreting excess of mucus, although no colitis is present. Achlorhydric gastritis and enteritis are indeed the most common of all causes of chronic diarrhœa, the loose stools often containing excess of mucus.

It is clear, therefore, that mucous colitis can only be justifiably diagnosed in the very exceptional cases in which mucus is passed with soft or liquid stools by a patient who is not taking aperients and who has not achlorhydria or enteritis. We must further exclude cases in which blood or pus is passed as well as mucus, as, unless carcinoma of the pelvic colon or rectum is present, ulcerative colitis or hæmorrhagic colitis will be found on sigmoidoscopic examination.

There is one condition which I have not yet mentioned—so-called muco-membranous colitis, in which the patient passes thin shreds or membranes, which sometimes form complete casts of a segment of colon several inches long. It occurs mainly in neurotic and constipated women, but it is a remarkable fact that whereas up to 1914 it was quite common among private patients, it has become exceedingly rare since the war not only in England, but also on the Continent (Boas). This is in spite of the fact that colon spasm, with which it is always associated, is as common as ever. The disappearance of the condition is as mysterious as that of chlorosis. Many years ago Dr. Gordon Goodhart examined several such membranes for me; they were formed of coagulated mucus and contained no inflammatory material, and the sigmoidoscope showed a perfectly healthy mucous membrane. The condition, which is most appropriately known as muco-membranous colic (not colitis), has many features in common with asthma. It depends upon abnormal irritability of the parasympathetic nerve-supply of the colon, and it is occasionally allergic in origin, the mucous casts representing the Curschmann's spirals expectorated by asthmatics, cases of pure colon spasm corresponding with the not uncommon cases of asthma, in which the secretion of mucus is very scanty.

I have seen only one case of muco-membranous colic associated with diarrhœa. This was a true allergic condition, the membranes being blood-stained and containing enormous numbers of eosinophil cells. The sigmoidoscope showed innumerable minute submucous hæmorrhages but no ulceration, and the mucous membrane was not swollen, red, and vulnerable as in ulcerative colitis. Complete relief followed the administration of a drachm of castor oil every evening and a drachm of Epsom salts every morning after numerous forms of specific and non-specific desensitisation and local treatment of the bowel had completely failed.

I hope I have succeeded in giving a clear picture of the normal human colon, as a thorough knowledge of its anatomy and physiology is the only sound basis for an understanding of its disorders and how to treat them.

BONE CHANGES SIMULATING TUBERCULOSIS OR TUMOUR

WITH SPECIAL REFERENCE TO OSTEOCHONDRITIS

BY JAMES F. BRAILSFORD, M.D. Birm.

HON. RADIOLOGIST TO THE QUEEN'S HOSPITAL, AND TO THE ROYAL CRIPPLES HOSPITAL, BIRMINGHAM

THOUGH the clinical signs and symptoms of bone disease are sometimes sufficiently characteristic to make a diagnosis possible there are few clinicians to-day who would venture to omit a radiographic examination. No one realises more fully than the radiologist that this is only part of the investigation, a part which must be a supplement to a thorough clinical study, and he is opposed to the current tendency to rely solely upon the radiographic findings. This tendency is carried so far in some cases that the clinician may be said to sacrifice his clinical observations for what he thinks he sees on the radiogram, or see in the radiogram shadows which appear to agree with what he found clinically. He will get the full benefits from radiology when he entrusts the interpretation to an experienced observer only, and discusses the radiologist's report in the light of the clinical findings which he supplies at a subsequent consultation.

Where such aids to diagnosis as the ophthalmoscope, cystoscope, or bronchoscope are in question every wise clinician relies upon the interpretation of men of experience; and with X rays too he will not substitute his own interpretation for theirs, even though his clinical findings are not in agreement.

Experienced radiologists are faced each week with problems which are difficult or insoluble, even with the aid of long experience and all the available clinical data; yet there are men without hospital experience who tackle such problems without hesitation though the radiograms before them are often of poor quality, and they may be ignorant even of the artefacts produced by faulty dark-room technique. And as poor radiology is usually associated with inferior clinical work it is not surprising that such an attitude leads to many unjustifiable errors, particularly those relative to tumour or tuberculosis. Thus cases have been published of ossifying periosteal hæmatomata which have been mistaken radiographically for periosteal sarcomata, with subsequent amputation of healthy limbs,[1] and I am acquainted with a number in which further X ray examination has saved the patient a long period of fixation for bone tuberculosis.

Common Sources of Error

Hæmatoma associated with the shaft of a metatarsal bone, most commonly the second, is produced probably by trauma so trifling that the patient does not suspect any bone damage. In the course of a few weeks the dorsum of the foot becomes swollen and he seeks medical advice. At this time a definite and relatively hard tumour may be detected, over which the skin is stretched and reddened. The degree of tenderness is not such as would lead to the suspicion of acute sepsis. A radiogram at this stage may show a flocculent deposit of calcium irregularly disposed around the affected metatarsal bone, which also shows a relative osteoporosis. No definite fracture line may be detected. These are the radiographic and clinical appearances which have led to amputation of healthy limbs. But if the affected foot is put at rest for a few weeks the swelling of the soft tissues will subside, the hardness of the tumour will diminish, and a further radiogram will show that the flocculent deposit of calcium in the hæmatoma has been moulded, and the typical "plumber's wiped joint" appearance of callus which is being trimmed down around the weakened metatarsal will be recognised as a healing process. I have recorded similar appearances in the long bones of the limbs which had been misinterpreted as evidence of malignant bone disease.

Healed localised foci due to *sepsis, tuberculosis* or *syphilis* present an irregularity in the ossification of the cancellous tissue sometimes associated with ill-defined deposits of calcium. The most frequent site to see these changes is in the lower third of the femur shaft. They, too, have been attributed to malignant bone disease.

Arthritis, especially of the spinal articulations or hip-joints, and even congenital deformities, are sometimes mistaken for tuberculous arthritis on insufficient grounds. In the early stages of tuberculous arthritis the bones may, it is true, show little or no radiographic change, but after a few weeks further radiograms will show definite signs of bone disease, and once destructive changes have been caused by this infection the bone never again appears normal, even when the lesion has healed. The diagnosis of bone tuberculosis should not be considered established until X ray evidence is obtained, and if radiography is used in this manner, the period of rest of non-tuberculous lesions can be determined by the clinical signs and symptoms, thus obviating a very long period of invalidism and the stigma of tuberculosis. This stigma may not only influence the patient's life—affecting such matters as occupation, life assurance, and marriage—but may also prejudice the diagnosis of other illnesses in the patient and members of his family, as in a case I have recorded. In actual cases of bone tuberculosis serial radiography is invaluable for watching the progress of the lesion and in this way assisting in the control of treatment.

Legg-Perthes Disease

There is a group of conditions collectively known as various forms of *osteochondritis* which have radiographic appearances especially liable to be wrongly regarded as evidence of bone tuberculosis. Lesions of this kind have been described in most of the *primary* and secondary centres of ossification before or after fusion of the epiphyses—that is to say, at all age-periods, though more frequently in childhood and adolescence—but the commonest site for them is the epiphysis for the head of the femur, where they give rise to Legg-Perthes disease. (Osteochondritis was distinguished as an entity in 1910 by several workers, including Legg, Perthes, Calvé, Waldenström, and Köhler.)

The signs and symptoms of this condition vary in severity, and frequently the early signs are transient. A history of trauma and an account of bouts of pain associated with a limp may be given, but often medical advice is not sought for many months after the onset of the symptoms. If, as occasionally happens, a radiographic examination is made in the early stage, the bone changes may escape detection and a negative report be given. With a few days' rest the signs and symptoms may disappear and the case be regarded as one of traumatic arthritis. But within a few months the patient is brought back again because the bouts of pain have become worse and more persistent. If radiographic examination is now made the doctor, unless he is familiar with the condition, will be shocked at the extent of the destructive changes depicted in the epiphysis, the adjacent extremity of the diaphysis, and sometimes in the roof of the acetabulum. In the light of these changes it is no wonder that the diagnosis of tuberculosis is seriously considered, especially as the general condition of the patient is usually below normal. Here, as in bone tuberculosis, serial radiography is essential, not only for the diagnosis but also for the control of treatment.

THE CHANGES SEEN

From an examination of the serial radiograms of over 70 cases I have drawn up the following record of the changes seen throughout their course.

The earliest radiographic evidence of Legg-Perthes disease I have been able to obtain is :—

(1) An *increase in the density of the femoral capital epiphysis*, usually associated with

(2) A *relative increase in the joint space*, the comparison being made with that of the opposite hip-joint which should always be included in the radiogram. This appearance is soon followed by :

(3) *Osteoporosis of the adjacent extremity of the diaphysis.* This may appear as : (*a*) linear zones of radiotranslucency following the lines of the principal bone trabeculæ, which appear to run obliquely downward and outward from the epiphyseal line ; (*b*) a zone of radiotranslucency of almost uniform depth across the proximal extremity of the diaphysis ; or (*c*) one or more circumscribed areas of radiotranslucency in the diaphysis near to, or abutting on, the epiphyseal growth cartilage or more distally situated in the neck away from the immediate proximity of the epiphyseal line.

The above three signs are usually to be found towards the end of the second month of the onset of symptoms. The prominence of Signs 1 and 2 gradually increases ; the joint space remaining about the same.

In my series there have been several cases in which radiography showed these signs and the patient gave a history of injury to the hip-joint area two or three months previously. A number of cases have also come to me several months after a radiographic examination at which these early signs had escaped detection, which is another strong argument for the inclusion of both hip-joints on the radiogram.

(4) *The dense epiphysis then begins to show signs of compression and impression fractures*, and this is followed during the next three months by

(5) *The appearance of fragmentation.* In this condition the epiphysis appears to be broken up into a number of dense fragments, and as the epiphysis has lost its homogeneity and capacity for withstanding the stresses and strains,

(6) *It is compressed and flattened still more.* Some of the lateral fragments may at this stage be squeezed over the end of the diaphysis and beyond the lateral margin of the roof of the acetabulum.

(7) *Gradual absorption of the dense islands* of bone occurs and

(8) *Compression and expansion of the proximal end of the diaphysis*, which is now beginning to fix more calcium, and consequently becoming denser; the osteoporotic zones are being obliterated or surrounded with dense margins.

Signs 4, 5, 6, 7, and 8 are to be found during the eighteen months of the disease. After that the radiograms will show—

(9) *A faint outline of a regenerated epiphysis* in which the dense fragments appear to be undergoing absorption for their outline cannot now be distinguished.

(10) Eventually *the last dense nucleus is absorbed* and in its place will be seen an area of relative osteoporosis.

(11) The extremity of the diaphysis shows increased deposition of calcium and obliteration of the osteoporotic zone.

Signs 9 and 11 are shown on radiograms taken during the 1½–4 years after the onset of symptoms, and while they are present, the epiphysis remains in a plastic state; consequently it may be deformed by pressure. Owing to the deformity of the femoral head the joint space is now irregular but not diminished. Usually during this period the patient has few or no symptoms of hip-joint disease and is allowed to run about without any support, or at most with the support of a calliper only. Hence it is not surprising that many of these affected femora become permanently deformed, for the plastic epiphysis is incapable of bearing the weight without giving way to some extent and becoming moulded over the expanded and compressed extremity of the diaphysis.

After the lapse of four years

(12) The cancellous structure of the epiphysis assumes the radiographic appearance of normal bone. Though the epiphysis and the adjacent diaphyseal extremity are compressed and deformed the epiphyseal growth cartilage does not disappear, as in those cases in which the epiphysis and diaphysis are involved in an inflammatory process, or in which a separation of the epiphysis has occurred. This is an argument against the suggestions that the process is due to sepsis or displacement of the epiphysis.

The study of a large series of these cases shows that the characteristic changes take place in bone which is within the capsule of the joint—i.e., the epiphysis, the roof of the acetabulum, and the proximal end of the neck of the femur. This suggests that the initial lesion leads to an alteration of the constituents of the synovial fluid within the joint which, as we have seen, is apparently increased in the early stages. The radiographic appearances suggest that the condition of osteochondritis results in a redistribution of calcium in those bones only which are associated with the fluid contents of the capsule. Thus we see that the epiphysis takes up calcium while the end of the diaphysis loses it, and later, when healing takes place, the flow of calcium is in the opposite direction. The bones outside the capsule show little or no change unless the picture is complicated by disuse atrophy. The nutrient foramen of the femoral shaft does, however, appear to be more prominent and perhaps rather larger than normal. A similar series of changes is seen in osteochondritis of the head of the second metatarsal. In contradistinction to tuberculous arthritis the healed articular surfaces are smooth though deformed, and bony ankylosis does not occur because the articular cartilage is not destroyed.

VARIATIONS ENCOUNTERED

Certain variations occur during the progress of the disease.

(1) The acetabulum may develop similar changes, either during or after the healing of those seen in the epiphysis. Following such changes the acetabulum is also compressed, a feature most clearly indicated at the upper lateral border where the bone projects beyond the normal boundary. In one case in the series these changes were not recognised until three years after the onset of the first signs. If the pelvic wall of the acetabulum is affected this may yield, and the condition of protrusio acetabuli develop. This is, however, more frequently associated with chronic arthritic changes of the rheumatoid type.

(2) Following the absorption of the epiphyseal fragments regeneration of the epiphysis may occur. The final appearances of the healed hip-joint depend on the stage at which the disease was recognised and the duration of rest of the affected bone from stress and strain during the plastic stage of the disease. In those cases in which the pressure has been evenly distributed over the plastic femoral head and acetabulum, the former is uniformly expanded, and the latter is flattened out and enlarged to accommodate the large femoral head. When the lateral fragments of the epiphysis are squeezed beyond the lateral border of the roof of the acetabulum, during the regeneration of the epiphysis, a displaced fragment also develops and eventually comes to lie with its medial border against the lateral border of the roof of the acetabulum. In this position it limits abduction. If the limb remains adducted during the plastic phase, the lateral aspect of the epiphysis may undergo more severe changes than the medial aspect. Any joint in which the disease has resulted in deformity of the articular surfaces works at a disadvantage and is not capable of bearing the stresses and strains of a normal hip-joint. Consequently such a joint develops the signs of traumatic arthritis at an earlier age than the opposite hip-joint.

DIAGNOSIS AND TREATMENT

Of the 71 patients with Legg-Perthes disease whom I have examined, 53 were boys and 18 were girls. In the boys the right hip-joint was affected in 23, the left in 26, and both in 4. In the girls, the right hip was affected in 11, and the left in 7. This distribution indicates that the disease is three times commoner in boys than in girls, but that the incidence on the two sides is about the same. The ages of the patients showing active stages of the disease ranged from three to fifteen years. One child, aged 2½, showed typical changes in the femoral epiphysis on the radiogram, but a year afterwards a definite septic arthritis of the hip-joint developed. Most of the patients showed the first signs of the disease between the ages of four and eight. In the first instance they all attended the out-patient departments of hospitals, and for the most part they were living in poor circumstances.

The most constant sign of this affection of the hip-joint is a *limp* which may be slight for weeks, and then assume such an importance that the parents seek medical advice. Though a limp could be detected in all the patients, pain in the region of the hip-joint was recorded in only 25 of the 71, and showed a wide range of severity. In some it was noticed for a short time on rising in the morning; in others it was present when the patient was standing or walking; in others, again, only after fatigue. In 4 cases the pain was so severe during the night that the patient was awakened and cried out. In 11 cases the patient also complained of pain in the region of the knee-joint.

These signs and symptoms were so intermittent and variable that a number of the patients had been put to bed for 1–4 weeks with the diagnosis of rheumatism. Then, because all movements of the limb were full and painless, they had been allowed their usual freedom, and this was always followed by a return of the disability. In 26 of the patients there was a definite history of a fall preceding the onset of the symptoms.

On examination it is found that the affected limb shows adduction and a somewhat prominent great trochanter. A flexion deformity of 10°–15° may be present, and if there is a long history of a limp or pain, the muscles of the limb will be under-developed compared with the sound side, giving a suggestion of wasting, though not to the extent seen in tuberculous arthritis. In some cases as much as ½ in. of shortening of the affected limb is detected, but in most of those in this series no such deformity could be found. As a rule the movements of the limb are free and painless even though there may be some spasm of the adductor group of muscles. Except in abduction and rotation, which are restricted, the movements are full, and as a rule no tender spot can be discovered.

In no condition is radiography more helpful than in these cases of localised rarefaction of the bones. A striking feature is that in the early stages the clinical signs and symptoms are usually, for a short time, so prominent that the negative radiographic appearance comes as a surprise; if changes are present they may be so slight as not to be recognised. Several weeks or months may elapse during which the child is allowed to play about before he is brought for further surgical inspection. The signs and symptoms may now be so much improved that the doctor is convinced the lesion, whatever it was, is healing. But when the radiogram is seen the appearances cause alarm.

The early clearance of signs and symptoms means that many of these patients are not brought for surgical advice until a definite and constant limp has developed; indeed, in my series the history and radiographic findings suggested that in the majority the hip-joint had been affected for several years. It is rare, therefore, to obtain a series of radiograms in which the commencement of the disease is shown. Periodic radiographic examinations will reveal the stage of the lesion and give an indication when the bone can safely be subjected to the normal stresses and strains. Radiographic histories of my patients, re-examined for the purpose of this paper, show that on an average the bone remains in a plastic state for over 3 years; the shortest time observed being about 2½ years and the longest 10 years. In the latter case the disease ran its course in one hip for 4 years and then began in the opposite hip, which has not yet completely consolidated. Another series of radiograms revealed that after nearly 4 years similar changes began to develop in the roof of the acetabulum of the affected hip-joint.

The accompanying Table summarises the results of my observations. The stages referred to under "appearances" are those already described.

Serial Radiographic Findings

Appearances.	Age of lesion judged from onset of first symptoms.	Condition of bone.
Signs 1–3	2–3 months.	Becoming plastic.
„ 4–8	3–18 „	Plastic.
„ 9–11	1½–4 years.	„
Sign 12	During or after 4th year.	Consolidated.

My reason for using the term "plastic" in these stages is that I have followed up the radiographic history of such hip-joints and found that the affected bone has shown the pressure deformities of weight-bearing as long as these changes persist. This would account for the statements previously referred to—namely, that even after immobilisation for two years the final result differed little from the limb allowed freedom from weight-bearing. I suggest therefore that the best results will be obtained in those cases which are recognised early and kept immobilised as long as the radiographic appearance suggests plasticity of the bone—even to the length of four years; I believe there is little justification for immobilisation during only a part of the time that the bone shows plasticity. In support of this contention I would point out that I have seen cases (exhibited by Mr. McCrae Aitken [2]) showing all the stages in the radiographic appearances here described. The patients were immobilised as long as the radiograms suggested plasticity and the final appearances of these hip-joints have been indistinguishable from normal. This immobilisation does not check the disease. The sequence of changes described takes place however the joint is fixed.

In view of the poor condition of many of the children, open-air treatment supplemented by light baths and good food is beneficial.

The operative measures devised and suggested by R. Whitman have not been generally adopted.

Bone changes similar to those seen in the capital femoral epiphysis in osteochondritis juvenilis occur in other bones, more particularly in the head of the second or third metatarsal bones, the tarsal scaphoid, and the semilunar. They all present typical radiographic appearances which have been described in another paper.[4]

DIFFERENTIAL DIAGNOSIS

In *tuberculosis of the hip-joint* the clinical features are usually prominent, including pain, marked limitation of movement, pain on manipulation, and wasting of the muscles of the affected limb. The radiographic appearances are distinctive. The most striking feature is the general osteoporosis of the bone in the neighbourhood of the joint, diminution of the joint space, erosion of the bone at the focus of infection, and later the separation of an amorphous sequestrum. Perhaps even more distinctive are the radiographic differences between healed bone tuberculosis and osteochondritis. Whereas the regenerated bone in osteochondritis takes on the internal structural appearances of normal bone, the bone which has been involved in a tuberculous process never again appears normal. The bone "scar" can be detected and the cancellous trabeculation of the neighbouring bone has a coarseness of texture which can readily be distinguished from the normal. If the articular surface of the joint has been attacked this will always be apparent from the radiogram. Bony ankylosis may result, whereas in osteochondritis the articular cartilage is not destroyed and fusion of the articular surfaces does not occur.

In *septic arthritis* there is high temperature, pain, swelling, local heat, and redness. On radiography at this acute stage the bones are apparently normal, but later general osteoporosis with separation of the head of the femur as a sequestrum or erosion and absorption of bone are usually seen. Finally, when the inflammatory stage has passed, bony ankylosis will become established.

Endocrine disorders.—In my book[3] I have illustrated that hypothyroidism is associated with delay in ossification and the appearance of multiple irregular osseous nuclei in the growing epiphyses. The appearance of these nuclei on radiograms of the epiphyses of such patients has been misinterpreted as the fragmentation stage of Legg-Perthes disease. Owing to their irregular ossification, these epiphyses may also undergo a very severe degree of moulding, even more severe than is seen in the worst cases of osteochondritis, a feature well shown in a paper on deformity in cretins by Berard and Novel.[5] The shafts of the bones in these patients are usually characteristic and a thorough clinical examination should make the diagnosis clear, for the changes are symmetrical and of an equal age-period.

Chondrodystrophies.—The defective ossification of the long bones in the condition which I described as chondro-osteo-dystrophy leads to some degree of dwarfism which is relatively symmetrical. In those cases in which the dystrophy is of a mild degree the dwarfing will not be so obvious. A certain amount of swelling may be apparent over the superficial joints and radiography will show, at certain ages, multiple osseous nuclei in the epiphyses with expansion and irregularity of ossification of the diaphyseal extremities. In this condition also the defectively ossified long bone extremities develop the deformities due to weight and strain, and as the radiographic appearances of these areas resemble some of those seen in certain phases of osteochondritis they are liable to be misinterpreted. Some observers therefore regard osteochondritis as a type of chondrodystrophy. A complete radiographic examination of the skeleton will show, as in endocrine disorders, symmetry of the changes at all ages, and an inquiry into the clinical and family history should make diagnosis possible.

Rickets.—The bilateral deformities of the neglected rachitic patient will be recognised on clinical examination and radiograms will show the typical changes.

Preiser's Disease of the Scaphoid

Following injury to the carpus circumscribed areas of osteoporosis may develop in the bones. I have seen these areas, for example, in the carpal bones, and the heads of the metacarpal bones, of men who have worked with compressed air drills for several years. As a rule the trauma is so severe that the patient is forced, by the pain and disability, to seek surgical attention soon after the accident. At this time it will often be found that there is a swelling over the region of the scaphoid which is tender on pressure. All movements of the wrist are painful. A radiogram may reveal no bone change in any of the carpal bones, but sometimes this is due to the position in which it is taken. The best positions to show the outline are (1) with the hand in ulnar deviation, or (2) with the back of the hand on the film, the skin over the scaphoid being the area of closest contact. Fine fissures in the bone may be obscured by the shadows of the overlying bony prominences or the general cancellous structure.

With the lapse of a few weeks all discomfort may have passed and pain is present only on forced hyperextension. As a rule, therefore, the patient does not come for treatment until the wrist is again injured, and though the trauma may have been much less the pain and limitation of movement is much greater. On examination it will often be found that the "anatomical snuff-box" is diminished or obliterated, and this area is very tender on pressure. Any attempt at forced hyperflexion or hyperextension causes pain. If the patient rests the injured hand the acute symptoms may subside, but he often seeks treatment later because of bouts of severe pain disturbing his sleep. Radiography at this stage usually shows a cyst-like area in the scaphoid with a fissure line running through it, but in some cases the cyst does not appear at first to be associated with a fracture line, and serial radiograms of some of these cases considered with their clinical histories suggest that a subsequent injury has fractured the bone through the weakened area. If several small circumscribed areas of osteoporosis were to be seen with X rays soon after the trauma, the radiograms will now show fusion and expansion of this osteoporotic area. Unless the wrist is put to rest the osteoporotic process will extend to the periphery and produce an apparent gap between the fragments. Even when this appearance is present it may be found that on surgical exposure of the carpus the scaphoid seems superficially intact, but incision into the cartilage will reveal fragments of dense bone within.

Osteochondritis Dissecans

The name "osteochondritis dissecans" was coined by König to describe conditions of the knee-joint associated with the separation of a small portion of the articular surface. He thought that as the result of a low-grade subchondral inflammation a fragment of the articular surface was separated from the condyle. As early as 1738 Alexander Munro had observed this condition and suggested that the separation of the loose body was due to trauma.

The lesion is usually found between the ages of 16 and 25, though sometimes later, and it is much commoner in males than females. Often it is bilateral, though one side only may show clinical signs.

Don King,[6] reporting on 24 cases, states that the average age was 18, and the condition was bilateral in 5. Most of the patients had complained of pain and discomfort for a year or two prior to submitting themselves for examination, the average interval being two years. There is usually a history of trauma some years previously, though the patient often seeks medical advice because of acute pain, swelling, and locking of the joint following a recent trifling injury. From histological examination of a number of the "loose bodies" removed King concludes that the lesion is due to necrosis with a low-grade productive aseptic inflammatory response. The "loose body" is, he thinks, caused by separation of a small fragment of the articular cartilage, though with histological examination he shows that the bed of the condyle containing it is covered with newly formed fibrocartilage and the "loose body" contains bone.

I have seen the separation of similar fragments of subchondral bone from the condyle of the femur in cases of tuberculosis of the knee-joint, but in these cases, while all the other bones of the neighbourhood show profound osteoporosis and the outline of the articular cartilage is blurred, the loose body retains the density of normal bone and preserves its sharp outline. Further, in some of the cases of osteochondritis dissecans the surgeon failed to find the "loose body," since it was covered by intact cartilage. My own opinion therefore is that the "loose body" is due to sequestration of a small fragment of subchondral bone. This separation might well be due to trauma and subsequent local vascular disturbances of the fragment. At operation the fragment from the articular surface may be free in the joint, may protrude into the joint but be anchored to its bed by fibrous tissue, or the articular surface may show a localised swelling of the cartilage, which may be fissured or eroded.

The history, as already stated, may reveal that for several years the patient has had intermittent pain, swelling, or discomfort in the knee and it may have been "locked" on several occasions. If the present signs and symptoms have developed immediately after trauma, the condition may be mistaken for rupture of the semilunar cartilage, while in those cases in which there is a long history of pain and swelling, tuberculosis of the knee-joint may be suspected.

The diagnosis of osteochondritis dissecans will be determined by the radiographic appearance. An ovoid shadow, slightly denser than the surrounding bone, will be seen lying in a shallow excavation on the lateral surface of the medial condyle of the femur. (Often it is slightly posterior to the midline.) Between the "loose body" and the condyle is an area of decalcification, and the bony walls of the bed are also denser than the rest of the bone of the condyle. There is no general rarefaction of the bones as in tuberculosis; in fact, unless the "loose body" is sought for, the normal appearance of the bones may lead to the condition being overlooked. As in other forms of osteochondritis, the first radiogram may show that the "loose body" has no increased density and the condyle is undergoing regeneration. It is rare to find these changes in the lateral condyle, but it is not unusual to find similar changes in the opposite femur though these may be symptomless. Changes do occur in the lateral femoral condyle which bear a resemblance, but I have found these only in association with recurrent slipping of the patella. The "loose body" may not always appear on the radiogram as a regular ovoid shadow, for irregular absorption of the calcium in the detached bony fragment results in a shadow with irregular borders or a flaky appearance.

King reported on cases in which, as the result of conservative measures, the condylar defect has been repaired. Sometimes a slight depression is found at the common site of the local destruction in the medial condyle, and this suggests that regeneration may have taken place.

Many other bone conditions present the clinical signs of tuberculosis or tumour. In some of them radiography will supply the evidence for the correct diagnosis and in all of them it will give useful information.

A HOSPITAL FOR LANCING.—Lancing, in Sussex, which has a population of 8000, is without a cottage hospital, and a movement is on foot to provide one. Worthing Hospital is too small even for its own districts and at Shorelands Hospital, Shoreham, only a few beds are available. The infirmary at East Preston is nine miles away.

GONOCOCCAL VAGINITIS IN THE ADULT

A METHOD OF ISOLATING THE GONOCOCCUS FROM THE VAGINAL SECRETION

BY AMBROSE J. KING, M.B. Lond., F.R.C.S. Eng.

AND

W. NEVILLE MASCALL, M.A. Camb., M.R.C.S. Eng.

CHIEF ASSISTANT MEDICAL OFFICERS TO THE LONDON COUNTY COUNCIL (WHITECHAPEL) CLINIC

THE theory that the gonococcus cannot survive in the adult vagina for long periods is usually advanced to account for failure to demonstrate this organism in the vaginal secretions. From clinical observations over a period of years we believe that the inflammatory changes in the vaginal mucous membrane which are so constantly associated with acute or chronic gonococcal infection of the cervix render this explanation improbable. The object of this paper, therefore, is to show that the gonococcus may, and often does, persist in the vagina, and that it is unaffected by the acidity of the secretion or by the prevalence of secondary organisms. Furthermore, it will be shown that the organism may be isolated from the vaginal secretion by a method we have devised.

The wall of the adult vagina, consisting as it does of a tough stratified epithelium with some occasional small mucous crypts but no true glands, is believed to possess or to develop a high degree of immunity to infection with the gonococcus and other pathogenic organisms. The canal is normally moist, and this is due to a whitish fluid which acts as a lubricant and consists mainly of desquamated cells. Protection against gonococcal infection is believed to be afforded by the acidity of this secretion, due to the production of lactic acid by the activity of the rod-shaped bacillus of Döderlein. It is generally agreed that gonorrhœal vaginitis does not exist alone, but is always associated with, or is secondary to, infection of the cervix or urethra.

The susceptibility of the vaginal mucosa to gonococcal infection decreases with age. Children are known to acquire the infection only too easily; adult girls are apparently less susceptible and competent observers have stated that gonorrhœal vaginitis is seldom seen in women who have borne children. Bumm[1] held that the vaginal mucous membrane becomes immune to the gonococcus after puberty, and according to Jadassohn[2] the vagina hardened by habitual sexual intercourse is only exceptionally infected. The statistics of Baermann[3] show that only 4·9 per cent. out of 1124 prostitutes were found to have infection in the vagina. On the other hand, Gurd[4] frequently obtained cultures of gonococci from vaginal swabs. In the opinion of Penrose[5] the vaginal fornices and especially the posterior fornix are sites where a gonococcal infection tends to become localised and to persist.

SYMPTOMS AND SIGNS

In the acute stage of gonorrhœa in the adult woman some degree of involvement of the vagina is a common finding, and in the nulliparous patient to whom sexual intercourse has not been habitual, it may give rise to symptoms of some severity. Besides a vaginal discharge, there is often considerable pain and discomfort on walking.

On examination the discharge is seen to be profuse and purulent, and there are obvious signs of vulval and urethral infection. The insertion of a vaginal speculum causes pain and the whole of the vaginal wall appears bright red, smooth, and glistening. Later, the lining epithelium may desquamate and form an adherent caseous coating to the free surface. Obvious signs of infection of the cervix uteri are usually present.

In the more severe cases of longer standing the papillæ of the vaginal mucous membrane are swollen and studded throughout with granulations, giving rise to a granular roughened appearance of the entire vagina. In the less severe type of case the inflammatory process may appear to be limited to the vaginal fornices, particularly the posterior fornix, and the upper part of the posterior vaginal wall. This localised vaginitis is common in the milder types of gonococcal infection, and especially in multiparous women. It is also seen as a stage in the progress towards cure of the generalised infection under treatment.

A form of vaginitis occurs in young girls which is particularly severe, painful, and intractable. In these cases, when specimens are obtained from the usual sites by the ordinary smear and culture methods, all attempts to isolate the gonococcus generally fail. Such cases are usually classified as "non-specific vaginitis" and, owing to the unsatisfactory response to treatment, are a distressing feature of all female venereal clinics.

Apart from this intractable group of infections, the vaginal mucous membrane, from the os uteri externa to the aditus, appears to develop a remarkable degree of immunity to gonorrhœa as the acute stage of the infection subsides. At this point the clinician may note a strong contrast between the inflamed and eroded cervix and the pale healthy looking vaginal mucosa. In the fornices, however, the inflammatory process may persist for a considerable period, and often lasts as long as the cervical infection. In such a case careful exposure of the posterior fornix will show the mucous membrane to be velvety, smooth, glistening, and bright red in colour. There is usually a thick purulent secretion in this area.

Faulty drainage and postural reinfection from the infected secretions of the cervical canal are contributary causes of this localised but persistent inflammation; yet the tardy response to treatment which this region shows seems to indicate some deficiency in local immunity. Many resistant cases and some "relapses" may be traced to neglect of this area in treatment.

THE CULTURAL METHOD

In attempting to isolate the causative organisms in these persistent vaginal infections we have employed the egg albumin agar medium, devised by Orpwood Price,[6] plated out in Petri dishes to give a large surface area for inoculation. The media in these dishes is sloped so that excessive discharge and moisture are able to drain away. This helps to prevent the surface of the medium from being overrun by secondary organisms.

The specimen is obtained by introducing a Cusco's vaginal speculum of appropriate size and pressing the blades firmly backwards and downwards into the posterior fornix. The speculum should be warmed before use and lubricants avoided, for these may be detrimental to the growth of the organisms by nature of their composition. In this way it is usually possible, on slightly opening the blades of the speculum, to obtain a quantity of the creamy vaginal secretion and to avoid admixture with the ropy mucus of the cervical discharge. Where difficulty arises in separating the two fluids it is advisable first to clear the cervical mucus with a swab on a Playfair's probe. The vaginal fluid is suctioned into a sterilised slender glass pipette (Wright's) fitted with a rubber teat. As much fluid as possible is obtained and expressed at once on to the surface of the medium. The secret of successful inoculation is *quantity*; tests carried out with small amounts of fluid, such as are obtainable with a platinum loop or a wool-covered probe, are rarely satisfactory.

The plates should be kept in an incubator at 37·5° C. for 30 minutes prior to inoculation and should be removed from the incubator only immediately before use. After inoculation the plate should be returned to the incubator and allowed to remain there for at least 48 hours. A strong mixed growth is obtained, among which the gonococcal colonies are identified by means of the oxidase reaction and then picked off the medium, transferred to a slide and stained by Jensen's modification of Gram's stain. The Gram-negative diplococci thus obtained may be subcultured and a pure strain isolated.

Morphologically and culturally the organisms are identical with the gonococcus obtained in pure culture from the urethra and cervix in acute cases. Gonococcal antigen made from the subcultures will, when titrated against a known gonococcal serum, give marked fixation of the complement. It must be emphasised that one negative plate culture is not satisfactory evidence that the gonococcus is absent. Several attempts may be necessary before the organism is isolated.

CLINICAL APPLICATION OF THE TEST

The diagnostic value of this test in supplementing the results of the urethral and cervical smears and cultures already in routine use may be estimated by analysis of the case reports of the first 263 cases in which it was employed. The total number of cases consisted of 151 married women, 108 single girls, and 4 widows. The 98 cases with positive plates consisted of 49 married women, 46 single women, and 3 widows (Table I.).

TABLE I

			Cases.
Total number of plates	263	Married	151
		Single	108
		Widows	4
Total number of positive plates	98 (36·8 %)	Married	49
		Single	46
		Widows	3

Of the 98 cases with positive plates, 44 were positive in the plates only (the corresponding gonococcal fixation tests, urethral and cervical cultures and smears being negative), and 12 were accompanied by a positive fixation test only. In 17 of the positive plates not only was the fixation test positive, but also urethral or cervical smears or cultures; whilst in 25 the fixation test was negative, but smears or cultures were positive (Table II.).

TABLE II

Plates positive only	44 (43·8 %)
,, ,, and fixation test positive only	12 (12·2 %)
*Plates positive, fixation test positive, also smears or cultures positive	17 (17·3 %)
†Plates positive, fixation test negative, but smears or cultures positive	25 (25·5 %)

* Analysis of the smears and cultures in this group showed:—

Positive urethral cultures	12	Positive urethral smears	2
,, cervical ,,	8	,, cervical ,,	3

† Analysis of the smears and cultures in the second group:—

Positive urethral cultures	14	Positive urethral smears	8
,, cervical ,,	10	,, cervical ,,	7

Naturally in some cases both smears and cultures were positive.

Of the 165 cases with negative plates, 101 were negative in all tests. In 24 there was a negative plate with a positive fixation test only, whereas in 12 the fixation test and smears or cultures were positive.

In 28 of these negative plates the fixation test was also negative, whereas smears or cultures were positive (Table III.).

TABLE III

Total number of negative plates	165 (62·7%)
,, ,, negative plates with all other tests negative	101 (61·2%)
Total number of negative plates with positive fixation test only	24 (14·5%)
*Total number of plates negative with fixation test positive and smears or cultures positive ..	12 (7·2%)
†Total number of negative plates with positive smears or cultures but a negative fixation test	28 (16·9%)

TREATMENT

Assuming from the clinical evidence that definite infection is the rule, and from the evidence of the bacteriological results that such an infection is often gonococcal, it follows that local treatment should not be confined to simple irrigation of the cervical canal, but that definite steps should also be taken to eradicate the infection from the vaginal fornices.

In general, it must be urged that all instrumentation and manipulation should be as gentle as possible, and that if antiseptics are used they should not be used in concentrated form. While the vaginal mucous membrane may apparently tolerate quite strong antiseptics without increasing the symptoms or causing discomfort to the patient, our experience is that the use of such chemical irritants will inevitably prolong the duration of infection. Thus we have employed a 25 per cent. solution of mercurochrome, but better results have been obtained with a 1 per cent. solution. Again, a 50 per cent. solution of ichthyol in glycerin is well tolerated, but our results with a 10 per cent. solution have been more satisfactory. Possibly the local immunity processes of the tissues are adversely affected by the stronger concentrations.

The following may be taken as a routine method of treatment of the vaginal mucous membrane and should be carried out in addition to urethral and cervical irrigations. The results will be found to be satisfactory in most cases:—

1. The vaginal fornices are carefully swabbed with cotton-wool pledgets soaked in a sterilised saturated solution of bicarbonate of soda to remove all discharge, mucus, and debris. The surface of the mucous membrane is then dried as well as possible with dry sterilised cotton-wool.
2. The whole surface of the mucous membrane is then carefully swabbed with a 50 per cent. mixture of glycerin and sterile water, or with one of the two weaker antiseptic solutions mentioned above. Careful manipulation of the speculum should ensure, by obliteration of folds and rugæ, that the entire surface of the infected mucous membrane is exposed to the bactericidal agent.
3. The vagina is loosely plugged with a gauze drain about a yard long which has been soaked in 50 per cent. glycerin or glycerin to which 3 per cent. Izal has been added.

It may be necessary to omit the gauze drain in patients who are pregnant, or in those who have recently suffered from inflammatory involvement of the uterine adnexa; in these cases the chronic stage of the infection is usually prolonged.

The treatment should be carried out daily, but if this is not possible some form of pessary treatment should be instituted. Good results have been obtained from foaming pessaries, such as Spuman with salicylic acid (Luipold-Werk, Munich), a stylus being inserted each night and followed the next morning by an antiseptic douche.

CONCLUSIONS

(1) Gonococcal infection of the vaginal mucous membrane not only occurs in the acute stage of gonorrhœa, but also persists in chronic form in the later stages of the disease. Thus in 53 (33·3 per cent.) of the 162 gonococcal positive cases the test was applied and the gonococcus isolated from the vaginal fornices in the chronic stage of the disease. The criticism may be levelled that by our methods it is not possible to obtain the vaginal fluid free from contamination by the infected cervical discharge. But the constancy of the clinical findings in the vaginal mucous membrane, combined with the fact that in 56 of our cases the vaginal plates only were positive, the cervical and urethral smears and cultures being negative, constitutes sufficient evidence to outweigh this consideration.

(2) The conspicuous clinical differences seen in the vaginal infection of children and young unmarried women as opposed to multiparæ, and others in whom the mucous membranes have been hardened, is merely a question of extent and severity of the infection. In the former types the whole length of the vagina is involved; in the latter, the infection usually becomes limited to the vaginal fornices.

(3) Severe infections of the vagina due primarily to organisms other than the gonococcus are much less common than is generally stated; the gonococcus is often present, although difficulty may be experienced in isolating it. (We except the group of vaginal infections due to the flagellate *Trichomonas vaginalis*.) In the difficult task of isolating the gonococcus in the "non-specific" group of cases, the vaginal plate method gives more satisfactory results than any other; in our series of 44 cases in which the plates alone were positive, 28 were of the severe generalised type of vaginitis, where repeated tests from other sites had proved negative.

(4) The theory of the "antigonococcal" value of a highly acid vaginal secretion in the adult must be abandoned. In our culture tests no inhibitory action appears to be exerted by strongly acid secretions. On applying a rough test of the reaction of the vaginal fluid, by litmus paper, of 100 cases in this series, 93 showed an acid reaction, 3 were alkaline, and 5 neutral.

(5) It is essential to utilise all the known tests in a suspected case of female gonorrhœa if a correct and certain diagnosis is to be established. If this vaginal plate method had not been employed 44 cases would have received an incorrect diagnosis.

(6) Treatment should be directed equally to the vaginal fornices as to the cervical canal and urethra if good results are to be obtained.

(7) This improved cultural method is valuable and essential not only in the diagnosis of gonorrhœa in the female, but also in the establishment of cure after treatment.

Our thanks are due to Dr. I. N. Orpwood Price, who has been responsible for performing the pathological tests.

achlorhydria was present at the second test-meal. (Fig. 3.) Although histamine was not injected, it seems unlikely that free hydrochloric acid would have been secreted by its injection, as the total acidity at no time exceeded 8 c.cm. of N/10 NaOH per 100 c.cm. of gastric juice. In my experience histamine has never stimulated a secretion of free hydrochloric acid if the total acidity at any time throughout the test-meal does not exceed 10 c.cm. of N/10 NaOH. Fig. 4 represents the final test-meal, when the typical curves as described for Fig. 2 is obtained.

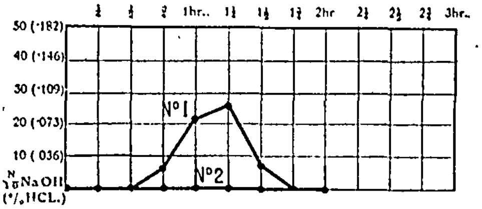

FIG. 3.—Case C. D. Curves of the secretion of free hydrochloric acid in November (No. 1) and in December (No. 2) one month later.

Coincident with changes in the secretion of free hydrochloric acid, definite alterations were found to be taking place in the motility of the stomach in these cases. It was found that an obstruction was developing at the pylorus. To demonstrate more clearly the development of this pyloric stenosis the following particulars are given in the accompanying Table : (*a*) the volume of resting juice obtained after complete starvation (including fluid) for twelve hours ; (*b*) the presence or absence of charcoal given twelve hours previously ; (*c*) the residue of the pint of gruel at the end of two ½ hours after 15 c.cm. had been removed every fifteen minutes.

Table of Test-meals showing Development of Pyloric Stenosis

CASE 1

—	Volume of resting juice in c.cm.	Volume of residue.	Charcoal.
November ..	44	Nil	Absent
February ..	55	35	,,
April	280	320	Present
May	720	400	,,
June*	220	340	,,
July	1400	400	,,
August ..	1350	400	,,

CASE 2

—	Volume of resting juice in c.cm.	Volume of residue.	Charcoal.
November ..	68	Nil	Absent
December . (1 month later)	230	160	Present

* In June at midnight, prior to the test, the patient vomited one pint of fluid, and this explains the drop in the volume of fasting contents.

The stomachs were examined in the Bland-Sutton institute of pathology.

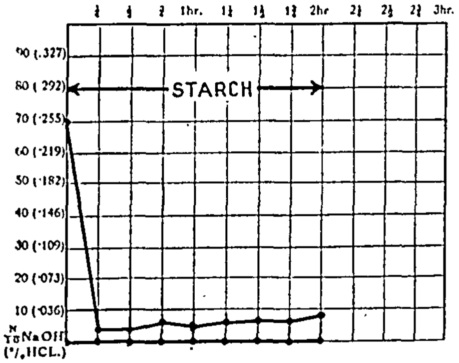
CASE 1.—To the naked eye the stomach was very much dilated and showed extensive involvement of the distal two-thirds by infiltrating new growth with obstruction to the pyloric canal. Sections of the growth showed it to be a scirrhous spheroidal-celled carcinoma. The mucous membrane proximal to the growth appeared somewhat thinned, but contained a fair number of oxyntic cells.

CASE 2.—The naked-eye appearance was that of a large chronic ulcer in the pyloric half with surrounding fibrosis. There was marked dilatation of the stomach with obstruction to the pyloric canal. From the microscopical appearances the pathologist reported that it was a very slowly growing carcinoma of the leather bottle type which had ulcerated and assumed the appearances of a chronic ulcer.

DISCUSSION

The views of Hurst have indicated the rarity of gradual disappearance of free hydrochloric acid in the presence of carcinoma of the stomach, and the fact that very few cases have been reported strengthens his contention. He has maintained that the achlorhydria, which is commonly discovered in carcinoma of the stomach, arose as a result of a gastritis which preceded the development of the neoplasm ; indeed, this gastritis is one of the commonest precursors of cancer of the stomach. I have, however, observed two cases of carcinoma of the stomach in which this alteration in gastric secretion took place.

The cause of the achlorhydria must be either the development of a severe gastritis or the spread of the carcinoma with destruction of the secreting mucous membrane. Of these two causes, the former would seem to be the more likely. The carcinoma is rarely so extensive as to warrant the opinion that it has completely destroyed the secretory glands, and further, achlorhydria has been known to be present with quite a small growth. In my two cases, histological examination of the stomachs showed that the carcinomas, although extensive, did not completely involve the glandular secreting mucous membrane. There is little doubt that the achlorhydria was due to a severe gastritis so intractable that constant lavage failed to produce any amelioration. While noting the change in acidity, it was observed that in both cases pyloric stenosis occurred, and it seemed probable that the stenosis had a bearing upon the other condition. It is suggested then that the cause of the diminution in free hydrochloric acid is an intractable gastritis consequent upon pyloric stenosis. If this were so, one would expect no such alteration in free hydrochloric acid in the presence of a carcinoma without pyloric obstruction. Unfortunately, I have not been able to observe such a case. That pyloric stenosis occurs rapidly is evident from the two cases reported where it can be seen to appear in so short a time as four weeks.



Volume of resting juice = 230 c.cm.
Volume of residue at end of 2½ hours = 160 c.cm.

FIG. 4.—Case C. D. Final curve in December (No. 2). Achlorhydria is present and the curve of the total acidity is shown.

The relative value of the detection of this change in gastric secretion has been discussed by MacLean and Shay and Schloss. They have stated that this development of anacidity is an early diagnostic feature of carcinoma, but they give no information about the operability of their cases when laparotomy, if any, was performed. In the two cases I report there was no doubt that when the first meals were carried out, the carcinomas of the stomachs were so extensive as to make operation impossible. The alterations in the secretions of free hydrochloric acid which were noted in the subsequent test-meals, while an interesting observation, cannot therefore be looked upon as having any therapeutic value.

CONCLUSIONS

(1) Two cases of carcinoma of the stomach have been described, in which free hydrochloric acid gradually disappeared; (2) parallel with changes in the free hydrochloric acid secretion were those in the motility of the stomach, and pyloric stenosis developed n both patients; (3) the cause of this diminution in ree hydrochloric acid appears to have been an ntractable gastritis secondary to the development of yloric stenosis; (4) this alteration in the curve of he secretion of free hydrochloric acid was of no ignificance from the point of view of an early liagnosis of carcinoma, for in both cases the carcinoma was advanced at the time the first test meal was erformed; (5) observations upon the development f pyloric stenosis showed that this could be rapid, uite advanced stenosis developing in four weeks' ime in one case.

My thanks are due to Prof. E. C. Dodds for his criticism, rof. S. L. Baker and Dr. R. W. Scarff for the histological eports, and Mr. E. W. Riches and Dr. T. I. Bennett for ermission to investigate their cases.

THE CAUSATION OF QUININE BLINDNESS

By EUGENE WOLFF, M.B. Lond., F.R.C.S. Eng.

PHTHALMIC SURGEON, ROYAL NORTHERN HOSPITAL: SURGEON, WESTERN OPHTHALMIC HOSPITAL: PATHOLOGIST, ROYAL WESTMINSTER OPHTHALMIC HOSPITAL

Two main views are still held with regard to the ay in which quinine affects the visual apparatus. It supposed (*a*) that it causes a spasm of the retinal essels and that the symptoms are due to the chæmia thus produced; or (*b*) that it acts directly n the retinal elements, the spasm of the vessels being econdary to this. No adequate reason is, however, iven for the spasm. It can hardly be due to disuse, nce it may come on soon after the taking of the drug.

On the tissues of the body generally quinine does ot act as a vaso-constrictor; if anything, it tends to ilate the vessels. Thus, C. R. Marshall[1] writes:—

> "On blood-vessels, quinine exerts an influence similar that on other contractile tissues. Perfusion of solutions quinine salts through the vessels of excised organs of arm-blooded animals (Kobert, Thomson), or through old-blooded animals (Wild), produce marked dilatation."

he fact that quinine is not a vaso-constrictor in the ody generally is strong evidence against its acting rimarily on the retinal vessels. Moreover, a large umber of cases have been described by observers of he first repute, where there was blindness without onstriction of the retinal vessels (von Graefe,[2] allantyne,[3] Fox [4]).

It is well known that quinine inhibits the oxidising power of protoplasm. "Thus it prevents the oxidation of guaiac resin when hydrogen peroxide or turpentine and some form of living protoplasm are added to a fine suspension of it in water. Under ordinary circumstances this turns blue at once; after the addition of quinine no change or but a slight one occurs." Also quinine diminishes the oxidising power of the blood and prevents or diminishes the reducing action of the tissues on the blood (Marshall). Binz (to whom we owe much of our knowledge of quinine) believed, indeed, that its action as a cell toxin was due to this interference with oxidation and showed that the changes produced in the lower organisms by quinine were similar to those produced by want of oxygen.

Whether we accept Binz's theory or not is immaterial. The point I wish to emphasise and I believe all are agreed on, is that it does interfere with the oxidation of the tissues.

THREE CAUSES OF SPASM OF THE RETINAL ARTERIES

An ophthalmoscopic picture of greatly narrowed arteries and a white disc, produced as an acute condition, much like that resulting from the taking of quinine, is seen following gastro-intestinal and other hæmorrhage, and also after division or block of the arteria centralis. It seemed to me that there might be some common cause of this phenomenon, and the fact that quinine hinders oxidation seemed to supply a clue. Hence I was led to inquire whether there was any evidence that in the other conditions diminution in the oxygen-supply might be the cause of the spasm of the retinal arteries and the white disc.

Loss of sight following *hæmorrhage* is commonest after hæmorrhage from a gastric ulcer. In the large majority of cases it is a recurrent hæmorrhage, and usually the blindness does not follow immediately on the hæmorrhage but comes on a day or more later, most commonly between the third and seventh day (Terson [6]). Amblyopia after traumatic hæmorrhage is extremely rare.

When a large hæmorrhage occurs anywhere in the body, the blood volume is made up much more rapidly than the corpuscles. It follows from this that for some time after the hæmorrhage the hæmoglobin percentage will be lower than at the time the hæmorrhage took place. In the normal person, in whom most traumatic hæmorrhages occur, the oxygen-supply to the tissues will gradually improve owing to the increased blood flow and after the blood volume is made up the hæmoglobin content will rise. In a gastric hæmorrhage, on the other hand, conditions are different. The hæmoglobin content of the blood of patients suffering from a gastric ulcer is on an average 75 per cent., as found by Friedman[7] in 50 cases afterwards verified at operation. After a gastric hæmorrhage, according to Crohn,[8] the percentage falls steadily for several days, and may go as low as 20. In a case of Whiting's[9] which resulted in optic atrophy the hæmoglobin fell to 15 per cent.

If we consider the probability that there are smaller unnoticed hæmorrhages—for Osler[10] says that the bleeding from a gastric ulcer usually recurs for several days—it is reasonable to suggest that in cases of blindness following hæmatemesis the oxygen-supply to the tissues generally and to the retina is actually less a few days after the initial hæmorrhage than at the time of its occurrence. Moreover, the onset of blindness is very often accompanied by giddiness, faintness, and even loss of consciousness, which are themselves symptoms of general oxygen-lack.

With regard to spasm following *block of the arteria centralis*, Uhthoff,[11] in two eyes which had to be removed for new growths but in which the media were clear enough for the fundus to be seen, had the opportunity of studying the effect of clamping the optic nerve (and thus the central artery) in the human. He found that each time he put the clamp on the optic nerve behind the globe there was a latent period of 5–10 seconds before the retinal vessels went into spasm. The same latent period was noticed when he divided the nerve. This seems to point to the spasm not being produced by the cutting-off of the blood current directly, but by the oxygen-supply of the retina falling below a certain point.

In the three conditions considered, therefore, the common factor seems to be an extreme oxygen-lack, and I suggest that this is the cause of the spasm of the retinal arteries. In quinine poisoning the cells are prevented from taking up oxygen, and probably also the blood gives off its oxygen less readily. In gastric and other hæmorrhages the oxygen-supply to the tissues is greatly reduced, and the same is necessarily true when the blood-supply to the retina is cut off.

ACTION OF QUININE

In the action of quinine on the retina two stages may, I think, be distinguished. In the first the quinine in its capacity as a general protoplasmic poison acts on the retinal elements directly. The loss of vision here may be slow or rapid, depending on the dose of quinine and the susceptibility of the individual. The second stage depends on the spasm of the retinal vessels, and I think is probably always acute in onset.

This two-stage action of quinine on the retina is borne out by cases in which it has been possible to study the symptoms and signs from the first. As Elliot[12] writes: "If a surgeon were on the lookout for the well-known symptoms from the first, it seems more than probable that he would find the loss of sight heralded by amblyopia, and constriction of the field of vision. This has certainly been the case in a few instances when close observation was possible." Moreover, contraction of the field of vision has been noted in medicinal doses of the drug.

Another problem which calls for explanation is the curious recovery of central vision. The patient may in fact eventually be left with normal central vision but with an extremely contracted field. It has been suggested that quinine affects the rods more than the cones, but this hardly provides a satisfactory solution. It seems much more probable that the answer lies in the vascular arrangements of the macula and fovea. The blood-supply to the ganglion cells is via the arteria centralis, and it is presumably by this route* that the quinine (at any rate mainly) reaches these cells. The small vessels which run radially from the superior and inferior macular vessels form (according to Leber) capillary loops which leave an avascular zone from 0·4 to 0·5 mm. at the fovea, and the rod-free area of central cones (bouquet des cones centraux of Rochon-Duvigneaud)[13] which subserve central vision occupy an area whose diameter varies from 0·15 to 0·2 mm. Thus the ganglion cells connected with the most central cones (which lie next the ganglion free central area) will be those which are furthest from their blood-supply.

It seems very probable therefore that the ganglion cells in the avascular area will be the last to be affected by the quinine and will presumably receive it in least concentration. Indeed, Druault[14] in his experiments on dogs found the macular ganglion cells much less affected than the peripheral ones.

The investigation of which this is a preliminary report is being carried out in the department of physiology, University College; and the pathological department of the Royal Westminster Ophthalmic Hospital. It has been made possible by a grant from the Medical Research Council.

A CASE OF INFANTILE COXA VARA

WITH NOTES ON THE ÆTIOLOGY

By J. Rowan Armstrong, M.B. Belf.

LATE HOUSE SURGEON, BELGRAVE HOSPITAL FOR CHILDREN, LONDON

THIS case may be worth recording on account of the "text-book" radiological appearance of the head and neck of the femur, showing the triangular fragment of bone typical of infantile coxa vara, first described by Elmslie in 1913.[1] Consideration of the ætiology raises several interesting questions about the ossification of this part of the bone.

A girl, aged 9, was noticed at school to be limping. She had no pain and very little disability, but the parents were requested to have medical advice. They had never considered the limp serious, and did not know when it first started, but thought it had been getting worse during the past six months. On examination the child was found to have a rolling gait with a fairly well-marked limp. There was 1 in. shortening of the left leg, with wasting of muscles of the left thigh. Movements of the left hip—50 per cent. limitation abduction, some limitation of adduction, and rotation. There was a compensatory scoliosis, easily corrected. Otherwise the child was normal and healthy. Radiography showed a left-sided coxa vara, with a triangular fragment of bone in the neck of the left femur (Fig. 1).

The case thus presented a typically insidious onset. From the history no accurate idea could be formed as to when symptoms had first appeared. There was no recollection of injury; indeed, the only incident in the child's life even remotely suggesting a serious trauma was the fact that she was born before the arrival of a doctor. The age at which symptoms first appear is usually stated to be between 5 and 10, and this child was 9. Examination showed the clinical features of a coxa vara, with nothing to indicate its cause. The diagnosis rests on recognition of the triangular fragment of bone in the neck of the femur seen on the radiogram.

A subtrochanteric osteotomy was performed, and the leg immobilised in suitable abduction by a double hip spica plaster. This treatment is on the same lines as that suggested by Fairbank.[2]

---

* I thought at first that this might be explained if the quinine acted on the retina via the vitreous, for the quinine would get into the vitreous via the ciliary body and would presumably affect the peripheral retina before the macular region. To test this, Dr. C. H. Hampshire kindly examined for me the vitreous of several dogs which had had quinine hydrochloride injected subcutaneously. In one case only was it thought that a trace of alkaloid could be demonstrated in the vitreous. But doubt was cast even on this when it was found that the normal vitreous fluoresced under filtered ultra-violet light even after being extracted with boiling ether and shaken with 2 per cent. sulphuric acid.

ÆTIOLOGY OF THE CONDITION

In considering the ætiology of infantile coxa vara the difficulty is to explain the presence of the triangular fragment of bone typical of the condition. Broadly speaking four possibilities suggest themselves.

(1) It might be the result of *trauma in infancy*, which passing unnoticed at the time, leaves a fracture which fails to unite by bone. This theory is open to several grave objections. First at birth the epiphysial line between the shaft and head is horizontal, and the neck is very short and thick (Fig 2, A). The anatomy of the whole region at this stage is against the possibility of a fracture being easily produced either close to the epiphysial line or at the neck. Then about one-third of the recorded cases are bilateral, and there seems even less possibility of an exactly similar trauma occurring on both sides, and without other signs, in a region which is not of a shape which suggests that it would be liable to trauma of any sort. I find no record of a child with infantile coxa vara having been treated for an injury in infancy; in the recorded cases there is a uniform absence of history of trauma. It is difficult, therefore, to believe that the condition is of traumatic origin.

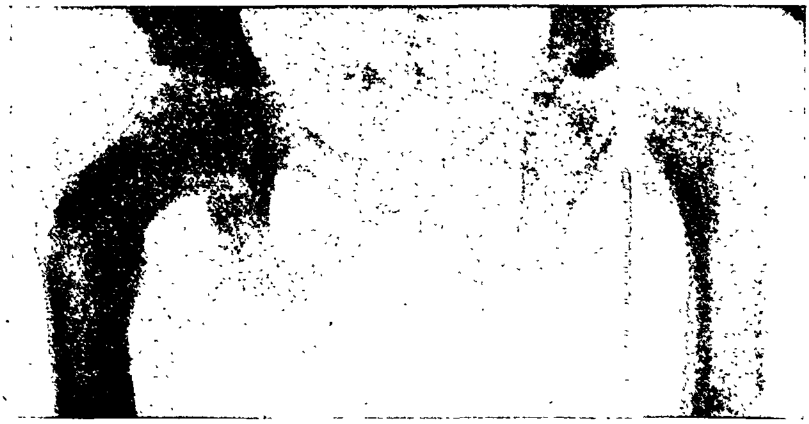

FIG. 1.—Radiogram showing left-sided coxa vara. The white line points to the centre of the triangular fragment of bone in the neck of the femur.

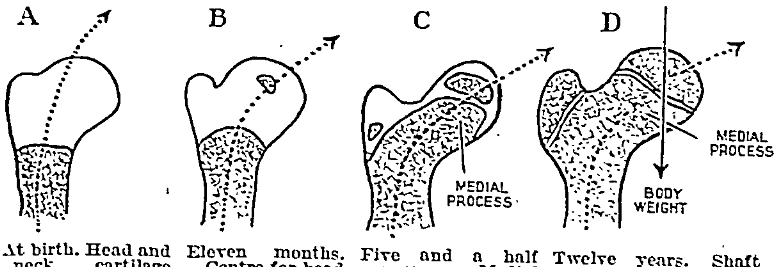
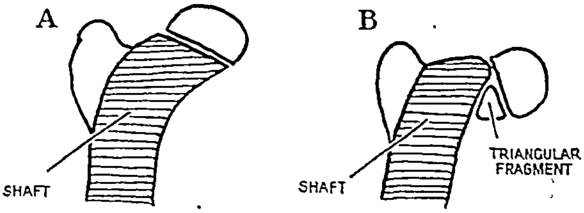
(2) There is nothing in the history of these cases to suggest any *metabolic disorder*. The primary lesion is limited to the femoral neck, and the patients are otherwise healthy with nothing to suggest any disease of the nature of rickets. This was so in the case here recorded; only in the femur did the child show any abnormal bony changes.

(3) The most probable explanation is *abnormal ossification of the neck of the femur*. In considering the development of the neck of the femur great stress is laid by anatomists on its being essentially a continuation of the shaft which grows upward and inward carrying the head like a cap on its extremity; it forms an angle with the main line of the shaft which is more open in infancy and closes as growth continues until in the adult it is about 120°. Prof. Walmsley[3] attaches great importance to the formation of a diaphysial spur or medial process of the neck which extends along the under surface of the head (Fig. 2, C and D). The head is, therefore, not only carried on the end of the shaft, but supported from below by this medial process. The formation of this spur increases the obliquity of the epiphysial line, making the shearing force of the body-weight act across this junction between the neck and head (Fig. 2, D). The space normally occupied by the medial process is in this case of infantile coxa vara occupied by a triangular fragment of bone. Fairbank[1] has suggested that in such cases this process may be formed from an extra centre of ossification, constituting a third element in the neck, and that this element, still ununited, is shown as a triangular fragment on radiography. I cannot find records of any animal in which such a third element in the ossification of the femoral neck has been observed. Walmsley's work on the ossification of the head of the femur tends to show that the introduction of a separate centre of ossification would nullify the morphological significance of this medial process.



At birth. Head and neck cartilage thick and short: not easily injured. Eleven months. Centre for head appears. Five and a half years. Medial process forming. Twelve years. Shaft has grown to form neck.

FIG. 2.—Diagrams illustrating formation and function of the medial process.



Normal. Upward growth only.

FIG. 3.—Diagrams illustrating suggested causation of triangular fragment in coxa vara.

I think that the coxa vara, with the triangular fragment of bone in the femoral neck seen in these cases, might be explained by an abnormality in the direction of the growth of the femoral shaft. The normal direction of growth is indicated in Fig. 3, A, where the neck is seen to form an angle with the main direction of the shaft.

Should the shaft grow upwards but not outwards (Fig. 3, B) there would be two results. First the head, no longer supported by the medial process, would sink down under the pressure of the body-weight, and a coxa vara deformity would result.

Secondly, there would be a triangle of cartilage which was ossified neither from the head nor from the shaft. Prof. Harris's work [4] on the formation and growth of bone indicates that such a fragment of cartilage could not persist as cartilage but must "degenerate" *into bone to obtain a blood-supply. Thus a fragment* would be visible on radiography, and if produced in this way the fragment must be triangular in shape (Fig 3, B).

It has been suggested that this triangular appearance may be an optical illusion, produced by an abnormal antero-posterior or postero-anterior obliquity of the epiphysial plane between the head and neck of the bone. Such triangular effects are sometimes seen, most commonly in the shoulder-joint, in X ray photographs. In the present case, however, the triangle seems to be a separate fragment on careful stereoscopic examination, and persists in all views of the bone, even when taken from different angles. It is therefore unlikely that it is not a separate fragment of bone.

I am indebted to Mr. B. H. Burns for permission to publish this case, and to Mr. S. T. Irwin, of Belfast, for his valuable comments.

FURTHER OBSERVATIONS ON THE "DIGESTIBILITY" OF COMMON FOODSTUFFS AS DETERMINED BY RADIOGRAPHY

By W. C. D. Maile, M.D. Camb.

AND

K. J. L. Scott, M.D. N.Z., M.R.C.P. Lond.

HON. PHYSICIANS TO THE WOKING VICTORIA HOSPITAL

The following experiments are a sequel to the work described in The Lancet of Jan. 5th, 1935 (p. 21).

The *method* was the same as used previously, half an ounce of barium being mixed with the food, to render it opaque, and the stomach being watched carefully by frequent X ray screening. The meals were all taken in the early morning to ensure the stomach being empty. The same subjects were used with the addition of one or two other volunteers. Four children of ages 5 to 8 were also examined.

Sugars when examined in detail gave some very surprising results, as *Table I. shows. It appears that* the emptying-time for sugar depends almost entirely on the amount of water taken with the sugar. Cane sugar with a small quantity of water takes more than half as long again to leave the stomach as the same quantity of sugar with ten times as much water. Glucose disappears from the stomach *less* quickly than cane sugar. Honey alone takes 4 hours to leave the stomach, but with half a pint of water leaves that organ in 1½ hours, as quickly as cane sugar. Presumable if cane sugar and glucose had been taken dry the emptying-time would have been much longer.

The fact that sugar in solution is absorbed so much more rapidly is a useful point to remember in the treatment of acidosis and hypoglycæmia.

One of us had a striking clinical confirmation of this a few weeks ago while playing golf with an opponent who suffered from diabetes. At the 12th hole the play of this gentleman became erratic, and he had to sit down as he said the landscape had become "wavy." In point of fact his morning dose of insulin had taken full effect. When asked if he had any sugar with him, his reply was, "Oh, yes, I've eaten several knobs of sugar, but there isn't any water, so it will be half an hour before I can go on, I'm afraid." He then volunteered the information that if he drank water with the sugar, he would feel all right again in a few minutes. We have since reduced his morning dose of insulin on golf days.

TABLE I

Food taken.	No. of subjects.	Emptying-time for each in hours.	Average.
Cane sugar 2 oz. .. .. Water 1 oz.	3	2½ 2¼ 2½	2⅜
Cane sugar 2 oz. .. .. Water ½ pint.		1½ 1½	1½
Glucose 2 oz. .. .. Water ½ pint.	3	2 1¾ 1½	1¾
Honey 2 oz.	4	4 5 3½ 3¾	4
Honey 2 oz. .. .. Water ½ pint.	3	1½ 1½ 1½	1½

Two children were given sugar meals and their stomach emptying-times determined. The results are given in Table II., and comparison made with the emptying times for adults.

TABLE II

Sex.	Age.	Food taken.	Emptying-time—	
			In hours.	For adults.
M.	8	Sugar 2 oz. Water ½ pint.	4	1½
M.	6	,, ,,	3¾	1½

It would perhaps have been better to give these two young boys doses of sugar proportionate to their age. But even so the difference in stomach emptying-time as compared with the adult is astonishing. The child's stomach does not deal with sugar nearly as rapidly as the adult's.

The stomach emptying-time for the various forms *of milk are shown in Table III.*

TABLE III

Food taken.	No. of subjects.	Emptying-time for each in hours.	Average.
1. Rich raw milk col. ..	3	3½ 3½ 3½	3½
2. *Skim milk cold*	2	2¼ 2¼	2¼
3. Rich milk boiled ..	3	2½ 2¾ 2¾	2⅝
4. Citrated milk	3	3 3½ 3¼	3¼
5. Peptonised milk ..	2	4 3½	3¾
6. Milk with sugar 2 oz. ..	1	3½	3½
7. Alkaline milk	2	3¼ 3¼	3¼
8. Milk boiled with Robinson's patent barley ..	4	3¼ 3¼ 3 2¾	3
9. Ditto, cold	2	3½ 3¾	3⅝

Notes.—(4) Sod. cit. grs. 2 per oz. was dissolved in a few oz. of the milk by warming and added to the main quantity. (5) Fairchild's powder used with 2½ oz. water and added to the warmed milk as maker's instructions. (7) Calc. carb. grs. 20, sod. bicarb. grs. 40, mag. carb. grs. 20. (8) Patent barley ¼ oz. added to the milk and boiled 2 minutes. (9) Patent barley ¼ oz. stirred into the cold milk.

The milk, except in the case of skim milk, was rich raw milk. Half an ounce of barium and half a pint of milk was used in all cases, except for alkaline milk, when a similar quantity of bismuth carbonate was used instead of the barium.

Cold skim milk—that is, milk with the greater portion of its fat removed—took 2¼ hours as compared with 3½ hours for cold whole milk. Whole milk boiled took distinctly less time to leave the stomach than similar unboiled milk. Milk boiled with patent barley must be compared, of course, with boiled whole milk, from which it appears that cereal additions actually increase the stomach emptying-time. None of the methods of modifying milk curd that we have tested, appreciably reduce the stomach emptying-time. Simple boiling is the only method we have found that shortens the time of stomach digestion of milk.

Two further experiments with milk were made on children (Table IV.):—

TABLE IV

Sex.	Age.	Food taken.	Emptying-time in hours.	Emptying-time for adults.
F.	7	Rich raw milk ½ pint. Barium ¼ oz.	3¾	3½
F.	5	„ „	4	3½

These experiments show that the emptying-time for milk in children is much shorter than in adults, when one takes into account the disproportion between the amounts given and the size of the stomach. We showed in our earlier paper that the adult stomach takes no less than 6½ hours to deal with a full pint of cold raw milk. These figures suggest that the stomach loses its capacity to deal quickly with milk as it grows older.

Patent milks, dried and condensed, were not tested. They are milks from which the water has been more or less removed, and sugar or starch added. It is clear from the observations quoted above that the emptying-time for any one of these will depend merely on its fat content.

Observations on the taking of fluids before and after meals gave interesting results (Table V.).

TABLE V

Subject.	Meal.	Stomach emptying-time in hours.	
		Fluid 5 minutes before.	Fluid 5 minutes after.
A	Tea, sausages, bread and butter.	4½	3¾
B	Coffee, cereal, milk 2 oz., egg, toast, butter.	4½	3¾
C	Coffee, eggs, toast, butter, marmalade.	4	3½

In these experiments exactly the same meals were taken on two consecutive Sunday mornings by each of the three subjects examined. On the first occasion the fluid part of the meal, half a pint of tea or coffee, was taken five minutes before, and on the second occasion five minutes after the meal. Except in the case of subject B the rest of the meal was taken dry. The effect on stomach emptying-time was extraordinarily constant, the time of stomach digestion in each case being reduced by half to three quarters of an hour. If the fluid had been taken half an hour before the meal, it is possible that the stomach emptying-time would have been found to be considerably longer.

CONCLUSIONS

(1) None of the usual methods employed to increase the "digestibility" of milk have much effect in reducing the emptying-time of the stomach, except simple boiling. (2) The child's stomach deals with milk relatively more quickly than that of the adult, and with sugar more slowly. (3) Sugar is much more rapidly absorbed from the stomach when fluid is drunk with it. (4) The taking of fluids *after* meals materially hastens the passage of food through the stomach.

Clinical and Laboratory Notes

ACUTE INGUINAL ADENITIS SIMULATING STRANGULATED FEMORAL HERNIA

By ALAN A. KLASS, M.D. Manitoba
RESIDENT MEDICAL OFFICER, ALBERT DOCK HOSPITAL, LONDON

THIS case caused confusion between two conditions commonly at opposite diagnostic poles.

A robust-looking stevedore, aged 37, was carried into the Albert Dock Hospital in the afternoon of April 3rd, 1935. At the age of 14 he had developed a tuberculous right knee as a result of which he had an ankylosed joint with a chronically discharging sinus at its lateral side. There had been no change in the condition of the knee in the last 20 years, and during the last 15 years he had not lost, by reason of his health, a single day's work as labourer on the docks. He had never noted a lump in his groin.

On the day of his arrival to hospital he had felt perfectly fit and was occupied in lifting bars weighing 100 lb. from the ground on to a platform. While in the act of raising one of these, he was suddenly interrupted by a sickly feeling followed by "going all of a sweat" and by a severe pain in his right groin. He sat down and shortly afterwards vomited his lunch. Unable to continue further with his work he proceeded to walk to the hospital, but the pain became so severe that he had to be conveyed by ambulance.

Seen at the casualty department of the hospital an hour after the onset of his illness he appeared shocked and complained of a pain which remained localised at its site of origin—present constantly but with severer exacerbations occurring every few minutes, at the height of which he felt nauseated. His temperature was 102·6° F., and his pulse-rate 86; he had several carious teeth and a tongue that was dry and furred. His right knee-joint was immovable and at its lateral side was a small sinus discharging a minute quantity of serous fluid. There was nothing about the appearance either of the knee or of the sinus to suggest a recent acute process. Aside from this the extremity was normal.

He indicated, as the site of maximum pain, an area corresponding to the region overlying the fossa ovalis of the right thigh. At this site a swelling could be felt and seen to rise about half an inch above the general contour of the thigh. It was however so acutely tender, and palpation caused so much distress, that an accurate determination of its character could not be made. There was no impulse on cough. In addition there was moderate rigidity with tenderness of the abdominal wall, most obvious just proximal to the right inguinal ligament and fading away at the level of the anterior superior spine. The urine was normal.

Despite the fever, which did *not* fit into the clinical picture of an early strangulation of an acutely occurring femoral hernia, and also in spite of the fact that the swelling was somewhat lateral to the usual site of emergence of a femoral hernia, it was felt that this diagnosis could not be excluded definitely without exploration. Accordingly under general anæsthesia a low *inguinal* incision was made, and the femoral canal was exposed. It was found empty. Overlying the fossa ovalis the subcutaneous tissue was œdematous and in its substance several enlarged pink inflamed lymph glands were exposed. One of these was removed for biopsy, and on section showed the typical microscopic picture of an intensive lymphocytic infiltration with numerous areas of hæmorrhage within the substance of the gland.

The post-operative course was relatively uneventful. The wound healed by primary union and the swelling tenderness and pain disappeared two days after operation. The temperature remained elevated at 102° for one day after the exploration and then subsided by lysis. An alveolar abscess developed in the right maxillary region and a small furuncle on the right ear, both of which readily disappeared. The patient left the hospital twenty days after operation, feeling quite fit.

There are several features of this case, the reasons for which must remain conjectural. What was the site of primary focus for the lymphadenitis? Radiography of the right hip showed no abnormality, while a plate of the right knee showed firm bony union between femur and tibia and a small sequestrum feeding the sinus. The character of the sinus and its discharge had apparently remained unaltered for years, and certainly showed no acute manifestations during the patient's stay in the hospital. Whether there was any causal relationship between the adenitis and the patient's occupation at the moment when his symptoms appeared so dramatically must also remain in doubt. And lastly, the very prominent gastro-intestinal symptoms which made this case so closely mimic an acute abdominal emergency cannot be explained with certainty.

I am indebted to Mr. D. Denham Pinnock for permission to report this case.

PITUITARY CACHEXIA

(SIMMONDS'S DISEASE)

TREATED WITH ANTERIOR LOBE EXTRACT

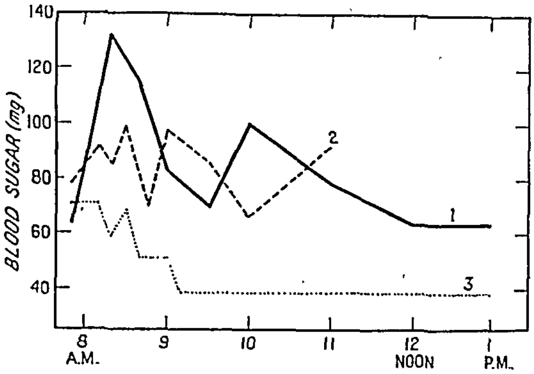
By Leo Rau, M.D.

FORMERLY ASSISTANT PHYSICIAN, RUDOLF VIRCHOW HOSPITAL, BERLIN

Various forms of endocrine therapy have been tried in cases of pituitary cachexia—e.g., thyroid and ovarian extracts—but none have been useful. In the following case an extract of anterior lobe of the pituitary proved efficacious given by mouth. The preparation used was dried anterior lobe containing all its fractions and not merely the identified sex and growth hormones.

The patient, aged 56, had had complete amenorrhœa for twenty years, dating from the birth of her third child. The labour had been normal and the temperature was normal during the puerperium. But after the confinement she lost all the hair on her head and body within a few months. There was also considerable loss of weight, but this had been regained during the past ten years, the gain being associated with œdema of her face. Within the last two years the patient had become very weak, with much fatigue, and was unable to walk. She felt very cold during summer and winter. Neither her memory nor her intelligence were impaired. There was no history of previous illnesses; her husband had met with an accidental death.

On admission the patient was found to have very pronounced œdema of the face and of the eyelids, general hæmorrhagic purpura, a very dry skin, and scleroderma on both legs. Downy hair was entirely absent; hair was missing from armpits and pubes, and was very thin on the top of the head. It was also lacking on eyebrows and eyelids. She was extremely weak, and typical symptoms of myxœdema were present though there were no serious intellectual disturbances. The urine was clear and showed neither albumin nor sugar (specific gravity 1008–1013). The blood pressure was 110/80, and the daily variations in her temperature were from 95·0 to 97·5° F. Radiography showed a pituitary fossa of normal size. Blood count: hæmoglobin 70 per cent., red corpuscles 3,700,000, leucocytes 5500 (polymorphs 42 per cent., eosinophils 3 per cent., monocytes 1 per cent., basophils 1 per cent., lymphocytes 53 per cent.). The B.M.R. (basal metabolic rate) was minus 40 per cent. on admission. Carbohydrate metabolism was upset, and the accompanying chart shows that blood-sugar values obtained under fasting conditions were abnormally low. The peculiar peaks which are common to all the curves are very striking. Patients like this are extremely sensitive to insulin, and in this patient the blood-sugar remained depressed for fully 24 hours after an insulin injection of 10 units despite a plentiful supply of carbohydrates. The cause of this sensitiveness to insulin is not known.



Curve 1 shows the readings obtained after the patient had taken 30 grammes dextrose at 7.50 A.M. Curve 2 shows the effect of adrenaline (gr. [illegible]
Curve 3 shows the effect of i
fasting. After the insulin
hypoglycæmic for 24 hours
grammes dextrose at 9.5 A.M.
on the curve.

The patient was first treated for three weeks with Thyroidein tabl. (Merck) 0·1 g. thrice daily but without success. At the end of this time the B.M.R. was minus 38 per cent. She was then given dried anterior lobe substance by mouth, and after two months' treatment the hair on head and the downy hair had begun to grow again. The œdema had entirely disappeared, and the patient was able to walk again and stand unaided. The B.M.R. had risen to minus 20 per cent. and subsequently reached minus 14 per cent. The fasting blood-sugar values had gone up to 80–85–90 mg. per 100 c.cm., and the daily range of her temperature had risen to 96·8–98·2° F. The improvement in the B.M.R., and the rise in temperature and in fasting blood-sugar values can be explained only by the influence of the anterior lobe treatment. The dosage was 150 mouse units a day for eight months with an interval of one week in every month. After this course of treatment, administration of extract was stopped for ten months, but it had to be resumed. After the extract was stopped she felt very well and fairly strong; but 10 months later she again became weak and was able to walk short distances only. Her hair became thinner and she lost weight again, but there was no œdema.

Swandean Isolation Hospital.—Proposals for extensions to this hospital at a cost of over £24,000 have been approved by Worthing town council.

REVIEWS AND NOTICES OF BOOKS

Nerve Regeneration

The Conduct and Fate of the Peripheral Segment of a Divided Nerve in the Cervical Region when United by Suture to the Central Segment of another Divided Nerve. By Sir CHARLES BALLANCE, Consulting Surgeon to St. Thomas's Hospital. London: Macmillan and Co., Ltd. 1934. Pp. 45. 7*s.* 6*d.*

IN spite of all the evidence that regeneration of a divided nerve occurs by growth of axis cylinders from the central into the peripheral segment, there are still some who admit the possibility that the peripheral portion of the axis cylinders can be reconstituted by some mystical activity of the neurilemma cells. Such a fallacy must surely be exposed once and for all by the account now published by Sir Charles Ballance of the nerve suture experiments carried out in the laboratories of the Royal College of Surgeons of England. When the central end of the cervical sympathetic was sutured to the peripheral end of the cut hypoglossal nerve, and after the time required for regeneration had elapsed, stimulation of the pupillodilator centre in the hypothalamus caused contraction of the muscles of the tongue. Such a result, though yielding interesting corroborative evidence of the presence of the sympathetic centre in the hypothalamus, could be explained on either theory of regeneration of the axis cylinders. But the chief value of Sir Charles's work lies in the histological study of the regenerated nerve, for he has shown that when the cervical sympathetic is sutured to the hypoglossal nerve the regenerated peripheral end contains only fine sympathetic fibres and therefore does not resemble the original hypoglossal nerve. On the other hand, when the central end of the hypoglossal nerve was sutured to the cervical sympathetic, the sympathetic fibres between the site of suture and the superior cervical ganglion were replaced by hypoglossal nerve-fibres, and the nerve became nearly twice the size of the original cervical sympathetic because of the greater size of the hypoglossal fibres as compared with those of the cervical sympathetic. In earlier experiments on nerve suture and regeneration, nerves were used whose axis cylinders were almost identical in size, and it was thus impossible to distinguish them under the microscope. But the use of the cervical sympathetic nerve, which has been sutured in different experiments to many of the adjacent nerves, has made identification possible, and the difference in the appearance of the nerve-fibres is clearly shown in the numerous excellent photographs and drawings which illustrate this book.

Treasury of Human Inheritance

Vol. IV.: *Nervous Diseases and Muscular Dystrophies.* Part I.: *Huntington's Chorea.* By JULIA BELL, M.R.C.P., under the Medical Research Council. Cambridge: at the University Press. 1934. Pp. 67. 10*s.*

A CRITICISM often levelled at eugenics is that we do not know enough about human heredity to justify even such limited action as the giving of genetic advice in individual cases. This reproach will gradually be emptied of valid content as the main categories of diseases recognised as being hereditary are covered by successive volumes of the "Treasury of Human Inheritance." The fourth volume of this monumental production, which is issued from the Galton Laboratory, University College, and is now edited by Prof. R. A. Fisher, is to be devoted to nervous diseases and muscular dystrophies; and if its parts maintain the high standard set by the first one, they will be received with deep interest by the widening circle of persons who see in the utilisation of our knowledge of human genetics the most helpful application of the principles of preventive medicine.

This monograph has twelve plates on which are very clearly reproduced 151 pedigrees of Huntington's chorea. The essential features of each of these pedigrees are set out in short descriptive notes which occupy more than half of the monograph. These notes are preceded by a very full chronological bibliography of 113 references ranging from the year 1658 to 1932. The value of the bare facts recorded in these pedigrees is greatly enhanced by Dr. Bell's introductory chapter. The salient points of the disease are here summarised under the following headings: signs and symptoms; age of onset; duration of disease and age at death; associated diseases; pathological incidence of the disease in the general community; and sex incidence and inheritance of the disease. These paragraphs are lucid, and—the average medical reader will be glad to find—are unencumbered by higher mathematics. As is generally known, Huntington's chorea behaves genetically as a simple Mendelian dominant; yet Dr. Bell's collection contains six pedigrees showing cases of chorea in sibships both of whose parents reached old age without showing any symptoms of the disease. Dr. Bell concludes her introduction by the remark that it would be contrary to all experience of hereditary affections if cases did not occur occasionally indistinguishable from those diagnosed as Huntington's chorea, but providing no evidence of the genetic determination of the disease; and she notes that she has chanced upon a few such cases in the literature. The hereditary nature of Huntington's chorea is so well known that such sporadic cases, though conforming in all respects to the typical picture, might escape the diagnosis of Huntington's chorea; and even if they were diagnosed, they would stand a smaller chance of being written up than would cases occurring in pedigrees showing other affected members.

Dr. Bell and Prof. Fisher deserve congratulation on an admirable production.

Recent Advances in Endocrinology

Second edition. By A. T. CAMERON, M.A., D.Sc. Edin., F.I.C., F.R.S.C., Professor of Biochemistry, Faculty of Medicine, University of Manitoba; Biochemist, Winnipeg General Hospital. London: J. and A. Churchill. 1935. Pp. 406. 15*s.*

MORE than any other field in medicine, endocrinology requires the close coöperation of clinician, pathologist, physiologist, and chemist, and their several techniques. The chemist, with his imagination and his precision, is mainly responsible for the speed and the extent of recent advances, and so it is fitting that a chemist should write the volume on endocrinology in Messrs. Churchill's series. Prof. Cameron's second edition brings the story up to August, 1934, and his handling of the riot of recent literature is masterly. New evidence is quoted or summarised simply and clearly, and not obscured by an over-conscientious attempt to be comprehensive. At each growing point he indicates how far the consensus of opinion has advanced, or what tentative conclusion the bulk of the evidence justifies. It is most instructive to watch the critical judgment of the pure scientist applied, with understanding, to the facts and problems of endocrine medicine. The most exciting chapter is, of course, the pituitary one. The anterior lobe is credited with eight distinct hormones, acting on growth, the sex glands, the thyroid, the parathyroids, the pancreatic islets, the adrenal cortex, the mammary glands, and the metabolism of fat, but suggestions are beginning to appear that other organs, such as the adrenal, the placenta (which is now the likely source of "prolan"), and the sex glands can in the reverse direction act on the anterior lobe. This would make the pituitary not the head gland of the endocrine system, but rather a nodal point in its network. We still await, however, a new idea which will give meaning to that network in the way that the conception of reflex action did to the nervous system. Prof. Cameron feels that much spadework must first be done, in the isolation and chemical identification of endocrine principles, before that stage is approached. Meanwhile his fascinating account of recent progress and the present state of knowledge is of the greatest value to all who are interested in endocrinology and especially to physicians.

Speech in Childhood

Its Development and Disorders. By GEORGE SETH, M.A., B. Edin., Ph.D., lately Assistant, Combe Psychological Laboratory and University Psychological Clinic, Edinburgh; and DOUGLAS GUTHRIE, M.D., F.R.C.S. Edin., F.R.S.E., Consulting Aural Surgeon, Royal Hospital for Sick Children, Edinburgh. London: Humphrey Milford, Oxford University Press. 1935. Pp. 224. 10*s.* 6*d.*

THIS work begins with a full and thorough description of the mechanism of speech, and of the problems connected with its representation in the cerebral cortex; the sounds employed in speech, and the methods of their production, are discussed, and the symbols used for these sounds by the International Phonetic Alphabet are explained. The ground having thus been cleared, the authors proceed in a long and interesting chapter to describe the development of speech in the growing child. They find, especially at the younger ages, that the measurement of vocabulary is a valuable means of estimating intelligence, for the results of vocabulary tests correspond closely with those of other performance tests. But retardation in the time of beginning to speak must not too readily be taken as a proof of mental deficiency; not a few cases like that of Thomas Carlyle have been reported, where a child has refused for many months to utter a single word.

The interrelation of speech and hearing is next discussed, and the problem of the deaf mute sympathetically considered; the authors believe that the retardation of the deaf child in respect of his native intellectual endowment is much less considerable than is commonly asserted. He is not deficient in intelligence but is deprived of the principal tool for making his intelligence effective. There follows a well written chapter on the disorders of articulation, dumbness without deafness, cluttering, lisping, and the like; and other chapters on nasal speech, rhinolalia clausa and aperta (the latter including the speech of cleft palate), on stuttering, and on the singing voice in childhood, including the problems of the "breaking" voice.

In a final chapter, on the organisation of speech clinics, the authors insist that a complete change of attitude to the spoken word is required on the part of the teacher and the school. It is most important to encourage attention to clear articulation and refinement of diction, especially in the education of children from homes or districts where the cultural level is low and where harsh and crude vocalisation and lip-lazy, slovenly, and uncouth articulation is the rule. We are entitled to demand of the elementary school-teacher, first, that she should herself be adequately equipped in respect of speech and voice; secondly, that she should have some knowledge of the psychology, physiology, and pathology of speech in children; and, thirdly, that she should give adequate time and attention to speech as such, and as distinguished from mere oral reading.

The book has been written throughout from a sympathetic and thoroughly practical point of view. It covers a great variety of subjects which, on the whole, do not receive adequate attention, especially in this country where "phoniatrie" has not hitherto assumed the position which it is attaining in the United States, France, or Germany. This book will help to draw attention to its claims and to improve the teaching of good diction, with all that this implies, to the rising generation.

Forensic Medicine

Fourth edition. By SYDNEY SMITH, M.D., F.R.C.P. Edin., D.P.H., Regius Professor of Forensic Medicine, University of Edinburgh. London: J. and A. Churchill Ltd. 1934. Pp. 644. 24*s.*

IN this the fourth edition of Prof. Sydney Smith's well-known book the text has been revised, though the original form is maintained and the subject matter retains its concise and informative nature. Among other useful features we would draw special attention to the good account, in the space of a few pages, of the principle and technique of the precipitin test for the origin of blood. The toxicological section, a matter of some 150 pages, has been generally revised. With regard to drugs of the barbituric acid group, which have recently been the subject of some controversy, there is an extremely useful table (taken from Mutch's work) which indicates the diversity of these products: the symptoms, treatment, and post-mortem findings of veronal poisoning are described as representative of this group. An appendix describes medico-legal problems peculiar to the East, with special reference to Egypt, of which subject Prof. Sydney Smith has an unrivalled knowledge.

Gould's Medical Dictionary

Fourth edition. By GEORGE M. GOULD, A.M., M.D. Edited by R. J. E. SCOTT, M.A., B.C.L., M.D., and C. V. BROWNLOW. London: H. K. Lewis and Co., Ltd. 1935. With illustrations and 174 tables. Pp. 1538. 30*s.*

IN a prefatory note to the first edition of this work that industrious lexicographer Dr. G. M. Gould referred to Simon Browne who 300 years ago "took to an employment which did not require a soul, and so became a dictionary-maker." He may have had good grounds for believing that the compilation of a book containing all "the words and phrases generally used in medicine and the allied sciences, with their pronunciation and derivation," is a soul-destroying occupation, but he is at all events entitled to the gratitude of those who have used his dictionaries and these now number nearly 900,000. There may indeed be more, for the figure quoted refers to sales. This fourth edition contains a new table of prefixes and suffixes used in medical terms, tables of bacteria, metazoa and protozoa pathogenic to man and animals compiled by Prof. D. H. Bergey, of Pennsylvania, and—which was quite a brain-wave on the part of the new editors—a transcript of the International List of Causes of Death. The changes and additions have been made by condensation without adding to the bulk of the volume which was already considerable, but for this bulk the present editors cannot fairly be blamed, and it will not be reduced until the coming of an International Academy (for which we have already prayed) which can quietly pack away and give decent burial to the many useless words in the medical vocabulary. There is only one word of criticism which applies not only to this but to all other illustrated medical dictionaries: the selection of objects to illustrate seems singularly arbitrary. On one page we may have the main features of cataracts, on the next a portrait of Darwin, and on another a picture of a separatory funnel. This ragged imagination does no credit to a compilation which has become a model of exact and logical presentation. There is a certain future for a medical dictionary illustrated with the same genius as that which marks the letterpress of the present Gould.

A New Angle on Health

Nature's Provision for the Health and Happiness of Mankind. By Surgeon-Captain D. H. C. GIVEN, M.D., D.P.H., R.N. (Retd.), late Medical Officer in Charge, H.M. Naval Base, Singapore. London: John Bale, Sons and Danielsson, Ltd. 1935. Pp. 160. 7*s.* 6*d.*

THE author of this book, being impressed with the difference in the quantity and character of disease among Asiatic labourers on the one hand, and naval personnel and white civilians on the other, attempts to find an explanation in the way of life of the two racial types. He condemns our Western civilization as built up on selfish greed, industrialism, and parasitism, and reflected in racial decay. While we have succeeded in eliminating the grosser ill-effects of environment, the "health heritage" and "sound body building" are impaired by urbanization, the decline of agriculture, extremes of poverty and riches, overcrowding, overfeeding, underfeeding, and improper feeding (called 'saccharism"). Because of man's biological wrongdoing, modern civilization hangs in the balance. The basis of industrialism is un-Christian and the remedy for our ills is obedience to the precepts of our faith. It seems to be implied that there must be an efflux from towns, a return to subsistence farming and unrestricted reproduction.

The author's method is declamatory and allusive rather than logical. Almost all the incontrovertible facts contained in the book are culled from the Registrar-General's Decennial Supplement to the Report on the Census of 1921, and if it serves no other purpose than to direct attention to that mine of information, it has been worth while. Except for the rather scanty but interesting data as to the health of Asiatic labourers in Singapore, the material of this book is familiar to statisticians, epidemiologists, and public health workers. Some of the explanations of observed phenomena are highly speculative and what the writer considers proof will not be generally accepted as such. It may be right that our rural population before 1760 was healthier than it is now, but it is not proven. We know, at least, that local famine was not uncommon in the days of the manor and village agriculture. If our survival as a race depends on a return to that way of life, the future is indeed bleak. If the author means that our competitive industrialism can be redeemed only by unselfishness and altruism, he is probably near the truth. Much of the statistical by-play is capable of different treatment, which might lead to other conclusions. That medicine and specific prevention are almost helpless against many of the influences of the economic and social conditions of our age is admitted; preventive medicine has reached this conclusion from no new angle and is slowly feeling its way to less revolutionary—or, shall we say, reactionary—means of amelioration than those propounded in the book under review. But more scientific examination of the facts is needed.

The Autonomic Nervous System

Second edition. By ALBERT KUNTZ, Ph.D., M.D., Professor of Micro-Anatomy in St. Louis University Medical School. London: Baillière Tindall and Cox. 1934. Pp. 697. 35*s.*

THE first edition of this book is so well known as a comprehensive guide to the literature of the autonomic nervous system that the main object of the reviewer is to note the additions to the earlier volume rather than to describe the work as a whole.

Until quite recently all the data bearing upon the functions of the autonomic system were collected from the results of physiological experiments upon lower animals, and a noteworthy change in the literature is the steadily increasing number of observations of the sympathetic functions in man. The change is reflected in this new edition of Prof. Kuntz's book. From the point of view of the practitioner its most interesting features are the references to recent work, carried out in the course of the investigation and treatment of patients, on the mechanism of micturition, on the conduction of visceral and referred pain, and on the effects of excision of portions of the sympathetic nervous system. The question of the existence of disease in the sympathetic ganglia in conditions which are benefited by ganglionectomy is well discussed, and the conclusion is reached that the variability in normal ganglionic tissue is so wide that no changes so far described can be identified as the pathological basis of a disease syndrome. In view of this laudably non-committal attitude it is surprising to read a few pages later that "Evidence is rapidly accumulating in support of the theory that pathological conditions of the autonomic nervous system play a rôle in the genesis as well as the course of some of the common vascular diseases, particularly Raynaud's disease."

Though recent advances recorded in it are many and varied, the volume serves only to emphasise the incompleteness of our knowledge of the source and pathway of the autonomic supply to the œsophagus, to the ureter, and to the cæcum and ascending colon, and of the exact distribution and function of the autonomic nerves to the distal colon. It is to be hoped that in the near future some of the anatomical and physiological investigations may be concerned with problems which are of pressing importance to the clinician. A feature of outstanding value in this book is the bibliography, but it should be arranged either in short lists at the end of every chapter or in one complete list at the end of the book: the present method of dividing it into several short lists at the end of the book leads to confusion.

A Text-book of Gynæcological Surgery

Third edition. By Sir COMYNS BERKELEY, M.D., F.R.C.P., F.R.C.S., Consulting Gynæcological and Obstetric Surgeon to the Middlesex Hospital; and VICTOR BONNEY, M.S., M.D., F.R.C.S., M.R.C.P., Gynæcological and Obstetric Surgeon to the Hospital. London: Cassell and Co., Ltd. 1934. Pp. 863. 45*s*.

A QUARTER of a century has elapsed since the first publication of this text-book and its continued popularity and usefulness entitles it to join the austere ranks of "standard works." The authors express the hope that their efforts may be of value to those who are proposing to follow this department of surgery and also to those who are called upon to perform gynæcological operations and have not had the opportunity for acquiring the ripe experience which accompanies long apprenticeship in the gynæcological wards. They could have added, but have not done so, that their book is so compiled as to be a real help to all who practise surgery in this region of the body, no matter what the duration and extent of their experience. Each operation is described in detail and so clearly that misunderstanding is impossible and in many places the reason for undertaking this or that procedure at a certain stage is carefully explained. The indication for each operation, the preparation required for it, and the post-operative treatment are fully described. The illustrations are numerous and some are magnificent. Chapters upon surgical technique, the operating theatre, and operations in private houses are included. The nature and treatment of post operative complications are allotted six chapters or nearly one hundred pages. In order to convey a correct impression of the relative dangers of the various operations the results of the work of twenty surgeons over a period of thirty years have been analysed. It is, however, the first few pages in the book that deserve the most attention and praise. The advice that is here given to the surgeon in regard to his conduct and behaviour toward the patient and in the theatre, the assessment of speed in operating, and the remarks upon operative manipulations could be repeated with advantage in every surgical text-book.

THE FERRIER LECTURE

HUMORAL TRANSMISSION OF NERVOUS IMPULSES

AT a meeting of the Royal Society on June 20th, Dr. Otto Loewi, professor of pharmacology in the university of Graz, gave the Ferrier lecture on problems connected with the principle of humoral transmission of nervous impulses. The following is an abstract of his address:—

In 1921 it was proved for the first time that the modifications of the heart's function, caused by stimulation of its nerves, are due to substances, liberated by the stimulation, called transmitters: acetylcholine and an adrenaline-like body respectively which in their turn bring about the effects of stimulation. This "humoral transmission of nervous impulses" occurs not only in the heart but also following stimulation of all the other vegetative nerves. Whether the phenomenon also happens within the somatic nervous system is not yet settled. The nerves releasing transmitters on stimulation do not influence the *function* of their effective organs otherwise than by this release. But we must attribute to them an influence—independent of the release of the transmitters—on the *sensitivity* of their effector organs to peripheral, directly applied stimuli. The discovery of the humoral transmission of nervous impulses discloses the hitherto obscure mechanism of the effect of nervous stimulation in general, and also particularly of peripheral inhibition.

THE PLACE AND MECHANISM OF RELEASE OF TRANSMITTERS

As to the point of attack of nervous stimulation, i.e., the localisation of the release of the transmitters, there are two possibilities: either the nerve-ending or the effective organ. There are many arguments against the latter possibility, but the former is supported by the following facts: (1) after nerve degeneration the transmitter disappears, even in cases in which the effective organ is not degenerated at all; (2) on stimulation of the preganglionic cervical sympathetic the transmitter is liberated, not within the ganglion cell, but at the synapse—in other words, from the nerve-ending.

Regarding the *mechanism* of the release we have to consider also two possibilities: either the transmitter is newly formed by the nerve-stimulation, or it is made diffusible, being split off from a combination already present in the nerve-ending. The decision between these possibilities cannot yet be made.

The lapse of time between the nerve-stimulation and the response of the reacting organ is extremely short, even in organs like the heart, where the transmitter has to pass a certain distance in order to reach the effector cells. The transmitters disappear somewhat quickly, the time of disappearance being dependent on the type of action which they have to produce.

The point of attack of the transmitters is not some part of the neurone but the functioning, effective organ itself. The fact that the transmitters, when artificially injected, mainly act at points in relation to which they are normally liberated, can be given, as yet, only a teleological interpretation. Since the transmitters can diffuse into the blood from the point of their release, they can, in principle, also affect remote organs, though under physiological conditions this may never happen. Obviously such a distant action is unnecessary, as such needs are fulfilled by the hormones.

DIFFERENCES BETWEEN THE ACTION OF HORMONES AND TRANSMITTERS

Finally, the question arises whether the difference between the action of the hormones and that of the transmitters concerns only the sphere or also the character of their action. The hormones of two of the ductless glands, both being neurotropic and differing from all other ductless glands by properties common to them only—the adrenal medulla and the posterior lobe of the hypophysis—initiate or modify, according to need, the specific *function* of the organs, as the nerves or the transmitters do.

None of the other ductless glands are neurotropic; their development and state depend largely on the anterior lobe of the hypophysis; their secretion is going on continuously and automatically, though partly controlled by the nervous system. Their action is concerned less with the *specific functions* of organs than with *general conditions*—state and metabolism. In other words, there are differences not only regarding the sphere but also regarding the character of the action of the nerves and the transmitters, on the one hand, and that of the hormones on the other.

THE LANCET

LONDON: SATURDAY, JUNE 29, 1935

THE PRACTICAL APPLICATION OF SPECIFIC PROPHYLAXIS

THE reasons why epidemic diseases successfully invade communities at one time and fail to catch on at others, and why they die out when there still appears to be enough inflammable material left to feed them, have been the subject of much interesting speculation among epidemiologists since HIPPOCRATES wrote his Books of Epidemics. The best informed writers of our own time are the least confident that we have found the true explanations. Laws have been postulated which epidemics seem to follow, only to be broken from time to time for no apparent reason. A glimmer of light has been thrown on the problem by the discovery that immunity, as measured by the skin tests of SCHICK and DICK, or by the statistical method used by STOCKS in the investigation of measles, whooping-cough and variola minor, can be acquired without even the mildest symptoms or signs of disease. The behaviour of the common infections of childhood, which smoulder continuously in civilised groups of people and burn more brightly at intervals, seems to be explained by the mixed reaction of the crowd to infection in the forms of typical cases, abortive cases, carriers, and what have been called latent infections. Unfortunately the extent to which any one of these groups of reactors will predominate cannot be accurately predicted, and there is no satisfactory explanation of the changes in virulence which infectious diseases appear to undergo, or the replacement of one type by another. The simple, and therefore attractive, view that man's nutrition and the healthiness of his mucous membranes govern the readiness and the violence of his reaction to infection fails to explain the steady decline in gravity of scarlet fever, the periodical recurrence of virulent forms of diphtheria, and the substitution of variola minor for variola major over a large part of the world. The work of bacteriologists indicates that variations in micro-organisms, and in their symbiotic associations, attend changes in the types of disease, but it is not safe to assume that conditions favourable to these changes do not arise in man himself.

Epidemiological history however shows that the eradication of disease need not wait for an understanding of all its idiosyncrasies. Man wages a winning battle when he can find some weak spot in the enemy's offensive. It is generally agreed that improvements in water-supplies, food handling, sanitation, and personal hygiene account for the decline of typhoid, paratyphoid, dysentery, and the other alimentary infections, and that cleanliness had probably more than nutrition to do with the disappearance of insect-borne diseases like typhus, relapsing fever, and trench fever. There is a school of thought which holds that these "natural" methods account also for the weakened virulence of scarlatina and the infrequency of variola major. But it is not natural to drink water, often chlorinated, brought in pipes from fifty or a hundred miles away, or to use water-closets or to wash the hands after defæcation. These procedures are, in a sense, specific measures against the diseases which may arise from their neglect. A hundred years of effort has shown us that they are unavailing against the large and persistent group of air-borne infections, whose prevalence or recurrence—with the exception of small-pox—has remained uncontrollable, although improved living and increase of knowledge have heightened the chance of recovery. Our good fortune in the matter of scarlet fever is no excuse for inactivity where diphtheria is concerned. Our freedom from variola major for a generation is no guarantee that it will continue.

Two years ago the public health committee of the British Medical Association, being impressed with the inadequate protection of the people of this country against variola major, recommended to the council and the annual representative meeting that the time had arrived to consider whether greater protection would be afforded by voluntary rather than compulsory vaccination. Without committing itself to this view, the representative meeting expressed its emphatic belief in vaccination and revaccination as the only effective methods known for preventing small-pox, and its readiness to consider any additional methods or variations of existing methods of encouraging their more extended employment. The council was instructed to consider any possible variations and appointed a committee not only for this purpose but also to explore the advisability of informing the public as to the various methods of immunisation against other diseases. Realising the magnitude of the subject, this committee has confined its attention to diseases prevailing in this country, or likely to invade it, for which methods of specific prophylaxis have reached a reasonable measure of efficacy and practicability. Its report[1] shows, by extracts from the Registrar-General's Annual Statistical Reviews, that the mortality from diphtheria has declined, especially since the use of antitoxin for treatment began, but the incidence remains unaffected, and the number of deaths in England and Wales still averages about 3000 yearly; the mortality from scarlet fever has fallen much more conspicuously, but there has been no decline in prevalence; measles, too, is much less fatal but still accounts for about 4000 deaths yearly; enteric fever has fallen to negligible dimensions both in cases and deaths; while small-pox as a cause of death has almost vanished, but the recent long wave of variola minor has revealed our vulnerability. An important part of the report is occupied with valuable descriptions of the procedure of immunisation against these several diseases, the prophylactics in common use, and the possibility of reactions and risks in their employment. The committee then discusses the much more debatable question of the application of these methods of prophylaxis to large communities, frankly admitting that what is good for the individual may not be good for the crowd. Weighing the evidence carefully it concludes that the experience of circumscribed institutional groups in this country and of general populations abroad justifies the opinions that harm has not been proved to be caused by creating reservoirs of virulent carriers, and that disease can be eradicated by mass-immunisation. Public prejudice against inoculations should therefore be overcome by every available means, including the constant influence of the family practitioner and educational propaganda by the Ministry of Health, local authorities, and voluntary bodies, stress being laid upon the haphazard and dangerous "natural" process of immunisation which skilled prophylaxis would replace. Lives would be saved if convalescent serum were used against measles, but no influence upon the periodical epidemics of this disease is to be expected. In the case of diphtheria, on the other hand, it should be possible to reduce both the incidence and mortality if rapid and sustained immunisation can be achieved. At present the mortality from scarlet fever is so low and the occurrence of the enterics is so inconsiderable, that it would be wise to confine immunisation to those persons who are abnormally exposed or belong to communities among whom these diseases create special problems.

---

[1] Report of Committee on Immunization, including Vaccination (Chairman: Prof. R. M. F. Picken). Supplement to the Brit. Med. Jour., June 22nd, 1935, p. 282.

Finally, the report turns to the question of vaccination against small-pox, showing how the "conscience clause" has reduced the percentage of vaccinations to births from 75·8 in 1905 to 38·2 in 1932. Immunity, since it wanes in each individual, must now be at a low level for the whole community, although revaccinations and the recent incidence of variola minor have induced it or renewed it in a certain number of people. Administrative measures for the detection and control of the disease are highly efficient, but they cannot safely be relied upon to cope successfully with every invasion which may occur in the future. Vaccination and *revaccination* afford the only security, but their compulsory enforcement is not practical politics. The present law is a sham. It is becoming less effective and the semblance of compulsion promotes antagonism. Its abrogation would make little difference. In any case, immunisation against the diseases dealt with in the report, and others which new knowledge may place in the same category, should be considered as one medical and administrative problem. Machinery should be maintained by local authorities for educating the public and putting prophylaxis at their disposal in a safe and convenient form. The power of the Minister of Health to make regulations appears to provide the necessary means of placing this duty upon authorities and of imposing compulsion in times of emergency, even if the present vaccination law is revoked.

The committee has confined itself to the practical consideration of the problems referred to it, touching upon the broader questions of epidemiology mentioned above only where it has been necessary to illustrate the line of thought by which its members have been guided. Workers in different furrows of the wide field of medicine will, no doubt, find some views with which they cannot agree, but the report will generally be welcomed as a moderate and authoritative statement of present-day knowledge and opinion on the prevention of the large group of infectious diseases which have not responded to improvement in environmental hygiene. It also reminds us that vaccination and immunisation can be fitted into public health law, and administration instead of being governed, as vaccination is, by inelastic statutes more appropriate to the old machinery of the poor law.

MATERNITY HOSPITALS

The women of this country are apparently deciding, rightly or wrongly, that they prefer to be confined in institutions rather than their own homes.[1] Every authority which has provided maternity accommodation, whether municipal or "voluntary," has found the demand for it soon outstrip the supply. It may therefore be expected that even more maternity beds will be provided in the near future than have been provided in the past. To those connected with such undertakings the information about the Willesden Maternity Hospital[2] now offered by Dr. G. F. Buchan, medical officer of health for Willesden, will be of great assistance. The building, he recalls, was converted in 1931 from a small-pox hospital into a maternity hospital with 31 beds, and the accommodation was increased to 64 beds in 1934, the total capital cost per bed being £728. Basic principles for the design, construction, equipment, and staffing of maternity hospitals have been laid down in the admirable Memorandum in regard to Maternity Hospitals and Homes issued by the Ministry of Health in 1920, and with the floor areas suggested in this memorandum for the different types of case Dr. Buchan is in substantial agreement, except that he suggests that the 60 sq. ft. per antenatal bed should be increased to 80. Out of the 64 beds at Willesden, the 53 lying-in beds are distributed in two blocks each containing a ward of 14 beds (one with a single-bed ward attached) and one block of two 7-bed wards. Dr. Buchan believes that the latter arrangement, with one single-bed ward and a nursery adjoining, is the best. There are five single labour wards for the first stage of labour, and three delivery wards. An isolation block of four single-bedded wards is provided, though cases of puerperal sepsis are removed to the Isolation Hospital. An antenatal block of 9 beds provides 1 antenatal bed to 4·8 lying-in beds, a proportion found to be a satisfactory minimum. In summary, Dr. Buchan considers that the ideal unit should have "lying-in beds, 60; antenatal beds, 12; isolation beds, 4 (provided that cases of puerperal fever are removed from the maternity hospital); labour block, 2 reception bathrooms, 5 labour beds, 3 delivery beds; operating theatre." On the basis of the Ministry's memorandum 23 nurses would be required to staff the 52 lying-in and antenatal beds, together with extra staff for labour and isolation blocks. The Willesden experience is that, assuming 13 pupil-midwives are equivalent to 8 nurses, a nursing staff of 22 working a 56-hour week suffices for the labour and isolation blocks as well as for the lying-in beds, suggesting that the Ministry's standard is on the generous side.

---

[1] The Lancet, April 20th, 1935, p. 942.

[2] Med. Officer, June 8th, 1935, p. 227.

An important feature of the Willesden maternity scheme is that, besides a resident medical officer at the maternity hospital, a consultant obstetrician is in complete clinical charge of all the maternity work including that of the ante- and post-natal centres. The supplementary notes contributed[2] by Mr. ARNOLD WALKER, the obstetrician in question, show that conservative treatment is the rule. Antenatal beds are essential, he holds, for the management of such conditions as the toxæmias, pyelitis, heart disease, antepartum hæmorrhage, debility, and "false alarms." At Willesden induction of labour is almost wholly restricted to cases of toxæmia; it plays no part in the treatment of disproportion in primiparæ. External version under general anæsthesia is no longer carried out; breech delivery in competent hands is considered safer, for both mother and child, than external version in which force is required. Low forceps is not an operation to be encouraged, in Mr. WALKER's opinion, but equally it is not to be feared; while anæmia due to loss of blood is more dangerous, he thinks, than manual removal of the placenta.

Municipal authorities requiring loans for the provision of maternity accommodation must submit their plans to the Ministry of Health, which can insist on essential units being included. It is much to be regretted that voluntary hospitals in similar circumstances do not make more use of the experience of the Ministry; for even quite lately new maternity units have been erected which omit antenatal or isolation accommodation or in which normal, abnormal, antenatal, and abortion cases are jumbled together in the same wards. The position as regards private maternity homes is often even worse, and the private practitioner who conducts a confinement in some of the houses at present registered under this name is taking on himself a very grave responsibility.

OXIDATION-REDUCTION POTENTIALS

IT is now rather more than 150 years since LAVOISIER announced that animal respiration is a process of slow combustion resulting in the liberation of heat; while in England at about the same time PRIESTLEY discovered the carbon dioxide assimilation of green plants. These two fundamental discoveries, the one of oxidation of carbon compounds by atmospheric oxygen, the other of reduction of carbon dioxide in the presence of chlorophyll and sunlight, were enough to show that life itself may be regarded as a process of continuous oxidation-reduction. Nevertheless, the fuller development of this conception had to await much greater knowledge of the sister sciences of chemistry and thermodynamics, and for nearly a century there was no extension of the scheme beyond a realisation of the need for maintenance of oxygen supply for animal life. Thus PASTEUR's "vie sans air"—the discovery that organisms could live without oxygen, by deriving their energy from fermentation-reactions in which this gas did not take part—came as a shock to the scientific ideas of his time. These fermentations, however, were also oxidation-reductions; but here, instead of oxygen being reduced and carbon compounds oxidised, one molecule or part of a molecule of the fermented substance was oxidised at the expense of another which was reduced. In PASTEUR's time it was impossible to formulate these ideas with much precision, and even to-day, despite the brilliant investigations of BUCHNER, HARDEN, MEYERHOF, WARBURG, and many others, there are links in the chain that are unknown or obscure. We may say that a desire to lighten this obscurity has been largely responsible for the modern development of our knowledge of oxidation-reduction potentials, which has been reviewed in a third edition of a recent publication[1] from the laboratories of the London County Council. The first edition was reviewed in these columns in April, 1931; and the rapid appearance of its two successors shows not only that Dr. HEWITT has succeeded in his task, but also that bacteriologists and biochemists take a lively interest in the subject.

The scientific study of these problems falls into two parts—namely, the isolation and chemical study of the enzymes and catalysts concerned, and the quantitative study of these oxidation-reduction systems. It is with the latter we are here concerned. These systems may be compared with electrical storage batteries, in which a thermodynamically reversible chemical reaction may be used to facilitate the transfer of electrical energy. They are characterised by electrical potentials which are often, fortunately, amenable to quantitative measurement by means of the potentials which they set up at an electrode. The electrical potential of such an oxidation-reduction system is akin to the potential set up by an acid-base system in contact with a hydrogen electrode. A number of standard systems have already been studied, and may be used much as standard buffer solutions are used in pH work. In addition, W. M. CLARK and others have extended the measurements to many coloured dyes, of which methylene-blue is the most familiar, which may be used as indicators of oxidation-reduction potential, according to the extent to which they undergo reduction to the colourless leuco-form under prescribed conditions. These substances in CLARK's hands have yielded very precise results, and offer a convenient method of studying oxidation-reduction potential. Naturally, when we turn to the application of these developments to the living cell, with its multitude of partially isolated enzyme and catalyst systems, we find ourselves in a vast new field where some lack of orientation is to be expected. But the many systems which are already yielding to exact treatment constitute a fascinating chapter of progress. It is true that many biological systems known to take part in oxidation-reductions have so far failed to yield to present knowledge and methods, but the scope of this type of study is evident from some recent discoveries. Glutathione, methæmoglobin, cytochrome, vitamin C (ascorbic acid), and adrenaline are all shown to form oxidation-reduction systems. More recently vitamin B_2, and the closely related yellow oxidation enzyme of Warburg, together with other flavins, have been added to the list. There is a suggestion that the physiological activity of the oxytocic hormone of the pituitary gland may be dependent on its behaviour as an oxidation-reduction system (GULLAND and RANDALL), and this suggestion is at present being examined. These and many other applications are of great interest to all connected with physiology and biochemistry, as are recent investigations into the oxidation-reduction level in the medium which is required for the maintenance of growth of cells in tissue culture.

---

[1] Oxidation-Reduction Potentials in Bacteriology and Biochemistry. Third edition. By L. F. Hewitt, Ph.D., B.Sc., A.I.C. Published by the London County Council. 1935. Pp. 90. 2s. Obtainable from P. S. King & Son, Ltd., 14, Great Smith-street, London, S.W.1.

The bacteriologist has contributed in full measure to the development of this subject, which has valuable applications in his own field. Almost all bacteria will set up an intensely reducing potential in their cultures; this is not surprising when the extent of bacterial metabolism is realised, a single cell of *Bacillus coli* being able to reduce 15 million molecules in each minute. A systematic study of electrode potentials in bacterial cultures has already revealed many characteristic mutual effects of organism and media. To take a single example, E. W. TODD in 1930 showed that the virulence of hæmolytic streptococci is maintained by opposing the reducing effects which they set up, and here a careful study of the oxidation-reduction potential of the medium is of great value. Thus as a technical aid in bacteriology the measurement of oxidation-reduction potential is at least comparable with that of hydrogen-ion concentrations. It is likely, however, that it will become much more than a valuable technique, and will make possible a more systematic and accurate description of biological oxidations and reductions.

ANNOTATIONS

INSULIN IN PERSPECTIVE

EVIDENTLY one of the ways in which the British Postgraduate Medical School intends to fulfil its purpose is to hold up any eminent man who may be visiting London for pleasure or profit and demand his coöperation. Some member of the staff with special claims on his attention is detailed to entice him into the far west and there to infect him with enthusiasm in doses lethal to his natural distaste, when on his travels, for anything like a job of work. The first fruits of these tactics was an open lecture at the school last week on the history of insulin by Sir Frederick Banting, F.R.S. The audience which filled the clinical theatre included medical visitors, as well as members of the staff, regular students, and practitioners assembled for the current "refresher" course; and their cordial reception of the first of the distinguished lecturers from distant lands to speak at the school was sufficient evidence of their gratitude, to which Prof. F. R. Fraser gave apt expression. Some of them were old enough to have sat helpless at the bedside of cases of diabetic coma, and only those, as Prof. Fraser said, could fully appreciate the wonder of the change brought about by the discovery of insulin.

It is now 14 years since the crucial experiments were made and more than 7 since Banting resolutely turned his attention from the pathology and treatment of diabetes mellitus to other problems. He can thus chronicle with detachment and in perspective the successive stages of the work between Oct. 30th, 1920, when an idea came to him, and Jan. 11th, 1922, when the first patients were treated with insulin. After four years' post-graduate work in surgery at various military and civilian hospitals Banting settled in general practice in London, Ontario, in July, 1920. He kept conventional office hours for 28 days before his first patient presented himself, and the next two months brought few others; but at the beginning of the academic year a part-time demonstratorship at the University of Western Ontario fell vacant and Banting was appointed. He decided to read for the F.R.C.S. of England or Edinburgh so as further to occupy his time while waiting for patients. One evening, after preparing a lecture on the relation of the pancreas to diabetes, he read an article in a medical journal on the degenerative changes in the pancreas which follow blockage of its duct by gall-stones or by experimental ligature; it occurred to him that these changes might make it possible to obtain an islet tissue extract undamaged by trypsin from the acini. He could not sleep that night; at 2 A.M. he got up and wrote in his notebook "Ligate pancreatic ducts of dogs. Wait six to eight weeks for degeneration. Remove the residue and extract." The tale of what followed has become history; those who want to read it in Banting's own words can do so in the *Edinburgh Medical Journal* of January, 1929. Last week he recalled only the salient points of the story: his visit to Prof. J. J. R. Macleod in Toronto to beg for 10 dogs, an assistant for 8 weeks, and facilities for doing blood and urine sugar estimations; the beginning of this work, some months later, with Dr. C. H. Best, then still an arts student, as assistant; their failure to obtain degeneration of the acinar tissue in the first batch of dogs and the repetition of the experiment with looser ligatures; and, only 3 months after the work had been started, success by means of extract of selectively degenerated pancreas in lowering the blood sugar and in improving the clinical conditions of a depancreatised dog. The attempts to obtain extracts of the islet cells free from the products of the acinar cells of the pancreas by more practical methods than duct ligation were detailed, and the steps which led up to the discovery that the active principle could be extracted from the adult whole gland with alcohol. Sufficient purified extract was obtained during the summer months of 1922 to prove conclusively the value of insulin to diabetic patients and the problem resolved itself into the best way to obtain the largest possible quantity of insulin in the best possible form at the cheapest possible price. At this stage the help of the Eli Lilly Company was enlisted for large scale production, and it was due to the splendid coöperation of this firm with the laboratory workers that the task of making the drug generally available was accomplished with such dispatch.

Commenting on associated problems, Banting said that the necessity for administering insulin by injection was not accepted without a struggle. Many other methods were tried; for example, in the attempt to avoid the destructive action of the digestive ferments insulin was given in capsules which would keep it coated until it reached the small intestine. But all such methods had to be abandoned as useless. There remain, he added in conclusion, a vast number of unanswered questions not only in the therapeutics but also in the pathology of diabetes. The most striking of these is the fact that enough insulin can be extracted from the pancreas of a patient dying in diabetic coma to have kept him alive if it had been administered through a syringe. Banting was thus at pains to disclaim on behalf of those working at diabetes the production of a complete story of triumph over disease. It belongs rather to that popular group of thrillers which records a series of exciting episodes culminating in a highly effective onslaught on an evil gang. That the strength and subtlety of the enemy's machinations are not, until the issue of the succeeding volumes, completely understood or entirely baffled only intensifies our admiration for the exploits of the leader of the first successful attack.

ŒSTRIN AND THE BREAST

In a Hunterian lecture delivered before the Royal College of Surgeons of England last February, Mr. Harold Burrows was able to show that œstrin has a remarkable effect in stimulating the development of epithelial structures in the breasts of mice. In the male mice used in his experiments the breast is normally represented by a few scattered ducts. The effects of daily applications of œstrin to the skin of these animals was to cause a budding-out of the epithelium, with an increase in the number of ducts and the formation of alveoli. Cystic dilatation of the ducts also took place, and sometimes a round-cell infiltration of the stroma; and finally, in the later stages, the epithelial lining of the ducts had proliferated so much that it definitely suggested the beginning of an intraduct carcinoma. It will be recalled that Lacassagne,[1] by injecting œstrin into the bodies of male mice, has produced a high incidence of mammary carcinoma, and has found that the actual proportion of the animals growing tumours varies with the strain to which they belong. Certain strains of mice are cancer-prone—i.e., as high a proportion as 72 per cent. of the *females* develop spontaneous cancer of the breast—while in others the incidence may be as low as 2 per cent. But in both strains the males developed tumours in response to œstrin; even in the strain with the low spontaneous incidence of 2 per cent., half of them developed cancer. A short account of the relevant histological changes appears in the April issue of the *British Journal of Surgery*, published there by Prof. Lacassagne's permission, as part of a communication by Sir Lenthal Cheatle. Forty-eight days after commencement of the injections the sections show dilatation of the ducts, which contain desquamated epithelium and a slight increase of breast tissue. By the 85th day the increase in breast tissue is obvious, and there are multiple cysts to be seen, while epithelial neoplastic cells with mitoses have appeared round the margins of the ducts. The sections at 143 days show the same picture in an exaggerated degree; the increase in breast tissue is now enormous, cysts are multiple, and the neoplastic cells are still within the boundary of the duct. At 179 days the section shows a well-developed carcinoma, and also intraduct growth at a distance from the typical carcinoma. Cheatle makes the important observation that carcinoma does not develop in the normal immature breast, but only in abnormal, new breast tissue appearing as a response to œstrin injection.

Even more extraordinary perhaps is Lacassagne's report[2] that he has been able to produce œstrus by injection of fluid expressed from small cysts in the non-cancerous part of a breast removed for carcinoma from a woman aged 57 years. An injection of 1·0 c.cm. of this fluid produced œstrus, while injection of an extract of the carcinomatous tissue in the same breast was ineffective.

ENZOÖTIC BOVINE HÆMATURIA

A DISEASE which is distributed widely throughout the world among cattle resembles what is known as "essential hæmaturia" when it affects man in that it is characterised by little or no systemic disturbance, and the passing of blood in the urine is the only obvious symptom. Consequently cases generally escape attention until the urine becomes markedly discoloured, by which time lesions within the bladder are fairly advanced. Actual diagnosis presents no great difficulty. Erythrocytes in the urine are usually intact and, unless there has been prolonged obstruction of the urinary tract, they are normal in size and shape. As the disease progresses, changes associated with anæmia appear; these become progressively worse and the bovine becomes extremely debilitated. Passage of blood in the urine need not be a continuous process. Frequently periods of apparent recovery are noted, but such periods are seldom of long duration; no case of spontaneous recovery has been recorded.

Numerous theories have been advanced to explain the cause of the disease. These include incorrect diet, malignant neoplasm formation in the bladder wall, plant poisoning, bacterial or helminthic agents. None of these explanations has been supported by convincing evidence. It has never been satisfactorily shown that the condition is infective or contagious; and the world-wide incidence of the condition makes it unlikely that plant poisoning is the cause. Of recent years opinion has veered towards the probability that the condition is due to some mineral deficiency. C. S. A. Datta[3] described a protozoa which he has located in the urine of affected animals and has identified in the bladder wall. The lesions in the bladder consist, in early cases, of small patches of congestion of the mucosa showing punctate hæmorrhagic foci and an associated thickening of the mucosa. Subsequently ulceration appears. In cases of long duration large proliferative growths of the epithelium are to be seen and cyst formation occurs. Microscopically the most striking condition is that of a congestion of the blood-vessels supplying the mucosa and submucosa. The vascular endothelium is deranged and serum exudes into the perivascular tissue. The resulting œdema is followed by localised necrosis and ulceration of the mucosa. Datta considers that the protozoa attacks the endothelial lining of blood-vessels, thus producing the primary lesion. When ulceration takes place these organisms are released into the lumen of the bladder after which an unsuccessful attempt at healing occurs. He also considers that the course run by enzoötic hæmaturia and the histological changes which occur show striking similarities to those of other amœboid infections. The parasite which he describes is to be found in both free and encysted forms. The cytoplasm is amœboid in form and contains a nucleus, karyosome, vacuoles, inclusion bodies, and ingested erythrocytes and particulate matter. Nuclear division has been demonstrated. Free forms vary in size from 10 to 60 microns, these being the smallest and greatest diameters measured. Cysts are somewhat smaller than free forms. It is thought that the organism falls into the genus entamœba. No report is given of the success of efforts to transmit hæmaturia artificially by means of this organism, but experiments with this object are being made.

B C G VACCINATION IN SWEDEN

IN 1927 the Swedish National Association against Tuberculosis initiated and paid for a comprehensive scheme of vaccination with B C G among the newborn infants of a district in the north of Sweden much ravaged by tuberculosis. The technique was that recommended by Calmette. Up to the end of 1933 the infants born in this district during this experiment, which is still proceeding, numbered 29,338, of whom 7765, or 26·5 per cent., were given B C G. In the same period there were 319 deaths among the vaccinated and 2101 among the controls,—death-rates of 4·3 and 10·8 per cent. respectively. The difference was less conspicuous when the deaths during the first five days of life were eliminated, but even then it was as great as 4·1 to 8·8 per cent. When the deaths were classified according to the ages at which they occurred, it was found that the difference between the two death-rates diminished with age; in the first year of life it was as 3·8 to 10·9 per cent., whereas in the second year it was as 1 to 2·1 per cent. In the third year it was as 0·5 to 0·8 per cent. The tuberculosis death-rate in the period under review was 0·1 per cent. for the vaccinated and 0·5 per cent. for the controls. The difference between the tuberculosis death-rates in the two groups was greatest among the oldest children. A classification of the deaths according as they were due to tuberculosis or other causes showed that B C G vaccination added little or nothing to immunity to infectious diseases other than tuberculosis. It has been maintained in some quarters that children given B C G are apt, as a class, to be more robust from the outset. To test the validity of this hypothesis, all the deaths from congenital debility were excluded from the statistics, and yet the difference between the death-rates among the vaccinated and the controls was as 3·8 to 6·8 per cent. Another explanation for the comparatively low death-rate of the B C G group is that the children in it enjoy greater care than the controls. Prof. Carl Naeslund,[1] who supplies the above-mentioned statistics, is not prepared to dismiss this explanation as invalid, but he adds that his colleague, Dr. Törnblom, who has been in close touch with the families concerned, believes that the children in the two groups enjoy the same care. Naeslund is not prepared to draw any conclusions from his material with regard to any immunity to tuberculosis which may be conferred by B C G; the unknown factors in this problem are too numerous to justify any such conclusion. But he feels sure that somehow or other B C G vaccination is of value in the campaign against tuberculosis. And he claims that after more than seven years' experience, nothing has happened to convict B C G of any ill-effects.

AGRANULOCYTOSIS

FROM Denmark Dr. C. Holten contributes further observations[1] to what is known of agranulocytosis. It has been recognised for some time that more women than men suffer from this disease, and Schultz, who described it as an entity in 1922, was inclined at first to think it was confined to middle-aged women. Holten's investigations, however, approach the problem of sex-incidence from a new angle. He finds that among the 3054 patients treated in his hospital in 1932 and 1933, a total of 352 were given amidopyrin (Pyramidon), and as many as 239 of these were women. In other words, the number of women receiving this drug was twice as great as the number of men, and if this ratio exists elsewhere, a simple explanation would be found for much, if not all, of the greater incidence among women. As 5 of the 352 patients developed agranulocytosis, anyone innocent of the pitfalls of statistics might be tempted to calculate that the risk of contracting agranulocytosis after taking amidopyrin is as 1 in 70; but Holten considers this an over-estimate of the danger, and would easily find support in this opinion. He also goes into the question whether agranulocytosis is a new disease, and is inclined to conclude that it is. In this connexion he refers to the retrospective comb-out by Lichtenstein of the records of the Stockholm fever hospital between 1916 and 1925. Among the 34,417 patients treated in this period there were 1449 deaths, but in the first five years not one of these could be considered as due to overlooked agranulocytosis. In the next five-year period there were at most 5 deaths—and probably only 1 or 2—which could be traced to this cause. Between 1926 and 1931, however, as many as 26 cases of agranulocytosis were diagnosed as such in this hospital. The experiences of the Blegdam's Hospital in Denmark point the same way, and the more conclusively as in this hospital blood examinations have long been carried out as a routine when any necrotic condition is found in mouth and throat. Here the absence, until the last few years, of records of what is now recognised as agranulocytosis can hardly be attributed to an oversight.

NARCOTIC ADDICTION IN INDIA

WRITING on drug-addiction in India Lieut.-Colonel Chopra[2] traces the history of the habitual use of narcotics from early times, but deals more particularly with experience since the report of the Royal Commission on the opium question in 1895, gained under the auspices of the Indian Research Fund Association. While the consumption of opium in British India is less than half what it was twenty years ago the administration of the drug to infants is still prevalent, and "is probably a cause of the high infant mortality in some communities." Thus "in Berar it is stated that 75 per cent. of the infants are doped with opium and 25 per cent. of the total opium consumed goes to infants." Addiction to

[1] Nord. Med. Tidskr., 1934, viii., 1659.

[2] Chopra, R.N.: Indian Med. Gaz., March, 1935, p. 121.

Post—the unlanced poppy capsules—apparently produces more pronounced physical, mental, and moral degeneration in the habitué than is the case with opium. It is estimated that in British India out of a population of 27 millions at least one or one and a half millions take opiates habitually; indeed, Chopra holds that most of the raw opium sold in the country is used for addiction purposes. Opium-smoking is more prevalent in Assam than elsewhere, and is discouraged by legislative and administrative restrictions. Resort to morphine is increasing, especially among young persons, while cocaine is smuggled into India in large quantities and its use is spreading in the large towns. The magnitude of the problem of drug-addiction in India may be appreciated by figures indicating that whereas in Europe and America the ratio of addicts to population is 0·1 or 0·2 per cent., in India the rate is 1 to 3 per cent. Colonel Chopra's researches certainly put a rather different complexion on the Indian aspect of the opium problem to that furnished by the report of the Royal Commission of 1895, which Lord Morley remarked had "somehow failed to satisfy public opinion or ease the consciences of those who had taken up the matter."

HUGH OWEN THOMAS

We reviewed at the beginning of the year a short book entitled "Hugh Owen Thomas: A Personal Study," by Frederick Watson, author of "The Life of Sir Robert Jones." The origin of the book was a discussion, shortly before his death, between Sir Robert Jones and Mr. Watson, as to the publication of a centenary volume dealing with the life and principles of the famous surgeon and bonesetter. It was then decided that the work should be done in two separate parts, one dealing with the environment and personality of the man and one dealing with his methods. The second volume now appears[1] from the pen of Mr. McCrae Aitken, and sets out how Thomas came to formulate his special treatments while tracing their influence on the practice of to-day. Mr. McCrae repeats, as is necessary to make the story coherent, many details of Thomas's early life in illustration of the way in which hereditary knowledge—he was the descendant of a famous line of Anglesey bonesetters—and personal industry made his practice so enormous and his position in the medical world so important, and this in spite of the fact that he never seems to have given any personal demonstrations, or any lectures explaining what he was doing and why he was doing it. "Looking back over the history of surgery in England during nearly sixty years," writes Mr. McCrae Aitken, "we can realise the loss of life and limb occurring in this country which might have been prevented if Thomas had come out of his shell and personally demonstrated his conservative methods of treating injuries and diseases of bones and joints and shown what he meant by uninterrupted rest." Robert Jones, as is well known, largely supplied this gap at a later date, and won by peaceful penetration a campaign which had failed under direct attack; not that Thomas led attacks, but he showed that when attacked he was splendidly capable of defence. Mr. McCrae Aitken epitomises Thomas's work, and in so doing shows it to have had a range quite unexpectedly large. His literary contributions and polemic correspondence prove him to have been fully conversant with the clinical medicine of the day, and to be especially strong on the details of the actual treatment of the sick by diet, nursing, and attention to environment. His name will always be associated with his systematic treatment of joint injuries and diseases, and for the splints which he devised to give effect to his methods, but the general message of this little book is that Thomas had a generally keen clinical acumen and a fine knowledge of physiological laws. His passion for accurate knowledge and his recognition of the principles of tissue life and repair made him seek fundamental rules of treatment. His appreciation of the value of rest drove his logical mind to reduce the management of certain groups of disease to a definite system, and to design splints to achieve his purpose with efficiency. Hugh Owen Thomas, M.R.C.S., was a club doctor, beloved by his own people, to whose service he devoted his strength and his life; he was a great surgeon whose tenets have now become a part of surgical routine, and he was a brave and simple man. Such was he whose centenary Sir Robert Jones planned to commemorate. The task has been well carried out by Mr. Frederick Watson and Mr. McCrae Aitken.

TYPHUS

Some interesting conclusions on the ætiology and historical epidemiology of typhus will be found in a book[1] by Dr. Zinsser which, as may be inferred from its title, is really intended for the layman. He considers that the two varieties of typhus—the "murine" and the "human"—are fixed, though very closely related, variants and that the "human" type is a relatively recent offshoot from the "murine," in which the rat-flea cycle precedes human infection. Both types coexist in Europe and America and also probably in many other parts of the world. The "murine" virus is maintained in inter-epidemic periods in rats and possibly in mice and occasionally causes cases in man from the bite of the rat-flea, but epidemics are only caused when the circumstances are such that human lice can transmit it from man to man. Individuals infected by the "human" type may have another attack many years later and epidemics may start under conditions of general louse infestation.

Historically, Dr. Zinsser considers, on rather slender evidence, that the first recorded severe epidemic in Europe was transported by soldiers from Cyprus to Spain in 1490; that typhus played a decisive rôle in the relief of the Imperial Army besieged in Naples by the French in 1528; reached its apogee in the Thirty Years War, and declined until the appalling recrudescence among the Serbs and in Russia during the great war. Dr. Zinsser concludes: "Typhus is not dead. It will live on for centuries, and it will continue to break into the open whenever human stupidity and brutality give it a chance, as most likely they occasionally will. But its freedom of action is being restricted, and more and more it will be confined, like other savage creatures, in the zoological gardens of controlled diseases." His book is described as a biography of typhus. It would be more accurate to say that typhus is used as a vehicle by which the author displays his literary and other prejudices. The medical reader will find the book well worth reading. It is both stimulating and unusual, and behind an at times almost unbearable discursiveness is concealed real erudition and knowledge of medical history. One is reminded of those Polish and Russian meals which begin with so many exciting hors d'œuvres and glasses of vodka that the actual dinner escapes attention. But it should not be neglected for it contains sustaining fare.

PHYSICAL ENERGY

We recorded last week the formation of a Central Council of Recreative Physical Training representative of various bodies interested in the welfare of young people. It is intended to survey the existing facilities for men and women as well as for adolescents and to prepare definite proposals for their coördination and development. Sporadic efforts are being made throughout the country to supply boys and girls who have left school and adults of all ages with some form of congenial physical recreation—gymnastics, swimming, sports, and so forth. But these efforts by no means cover all districts, or provide for the needs of all groups of inhabitants. For instance, there are youths and girls in the country who do not feel moved to join scout or guide movements, and others, in towns, who have no impulse to belong to clubs or attend evening institutes, and are thus not eligible for the facilities for physical recreation provided in association with them. Even where opportunities for exercise are provided, the lack of expert assistance often prevents their full use. At the present time the standard of training and equipment of such teachers and leaders as are available varies within wide limits. Intensive courses of training will doubtless be instituted as one of the first activities of the new council. If these are wisely planned and not too ambitious in scope they should attract a large number of potential leaders, on whose help the success of evening centres as well as of playing fields largely depends. It has been something of a disappointment to those who have striven hard to provide open spaces for games to find that not only space but a stimulating organiser is needed; in the absence of anyone to make suggestions for different kinds of play and to help to carry them out not only children but adults tend to get bored and to go away. A discerning and experienced observer will, moreover, be able to help those who may have no interest in games but enjoy keenly athletic sports such as running, jumping, or throwing which demand endurance, nice judgment, or swift decisions. It is to be hoped that those of middle age as well as the young will be catered for when new plans are being made, especially middle-aged women. Except in well-to-do circles, where women well over 50 habitually ride and swim and play golf or even tennis, there is still a tendency to find something comic in the idea of their taking physical exercise; but where, as in certain village institutes, the older women are encouraged to play games or join in country dances the improvement in mental as well as physical alertness and well-being is quite remarkable.

Already, we understand, the response to the idea of a central organisation which will encourage the development of all existing activities in such a way as to avoid overlapping has been most enthusiastic, especially from workers in recreational gymnastics. There can be no doubt that the formation of a national coördinating scheme will act as a stimulus to local effort, provided that no misguided attempts are made to reduce it to a standard pattern. The temporary office of the new council at 11, Doughty-street, London, W.C., is already proving too small to deal with its rapidly growing business, and it is to be hoped that when the Jubilee Trust fund is distributed the council will be able to enlist its support so that suitable headquarters and an adequate office staff will be secured. We believe that the new organisation will be a powerful agent in promoting national health and happiness.

CALCIUM THERAPY IN EPILEPSY AND MIGRAINE

There is little agreement about the rôle of calcium in epilepsy. Griffiths[1] has shown that sodium sesquiphosphate, which lessens the blood calcium, will cause an increase of fits, and this suggests that attempts should be made clinically to raise the level. This is not so easy to achieve, but Untersteiner[2] of Salzburg nevertheless claims excellent results from prolonged administration of large doses by mouth. He uses the double lactate of calcium and sodium, believing that the sodium lactate promotes the absorption of calcium and prevents the anorexia, constipation, and abdominal pain that would otherwise result. His plan is to give fifteen grammes of the double salt daily. For 6–8 weeks the previous dose of Luminal or bromide is given as well, but it is then gradually decreased and finally withdrawn altogether. Out of 49 epileptics treated for a period of a year or more, 22 were freed from their fits by this method, 17 were greatly improved, while in only 10 the treatment failed. As one would expect, the patients who had frequent slight seizures showed the least response.

Untersteiner treats migraine with similar doses of the double lactate, to which he adds small amounts of amidopyrin, luminal, and caffeine citrate. Here again after the first 6–8 weeks, first the luminal, and later the amidopyrin and caffeine are gradually lessened and withdrawn. Out of 27 cases he claims complete freedom from attacks in 7, much diminution in their number and severity in 11, and some improvement in 4; there were 5 failures. The value of this work would have been greatly enhanced by blood calcium estimations.

Prof. Otfried Foerster, of Breslau, will deliver the Hughlings Jackson lecture at 8.30 P.M. on Wednesday, July 31st, at B.M.A. House, Tavistock-square, London, W.C.

Mr. Walter Elliot, M.B., Minister of Agriculture, has been elected a Fellow of the Royal Society under the special statute which admits "persons who have rendered conspicuous service to the cause of science or are such that their election would be of signal benefit to the Society."

Prof. A. J. Ballantyne of Glasgow is giving a course of six lectures at Basle, Switzerland, on the histological interpretation of the appearances of the fundus oculi.

A Conference at Royat.—It has been decided to hold an international meeting at Royat, France, every third or fourth year, for the discussion of cardiovascular disorders. The subject of the first, to be held next Whitsuntide, will be Vascular Spasm, and the lecturers will include Prof. C. Heymans (Ghent) and Dr. L. Brouha (Liége), Prof. Riser (Toulouse), Prof. R. Leriche and Dr. Fontaine (Strasbourg), Prof. Marañon (Madrid), and Prof. Loeper (Paris).

PROGNOSIS

A Series of Signed Articles contributed by invitation

LVIII.—PROGNOSIS OF PUERPERAL INSANITY

THE conception of "puerperal insanity" as a mental disease peculiar to the childbearing woman enjoys a protracted funeral. No such disease exists; pregnancy, labour, and the puerperium are properly regarded as precipitating or associated causes of breakdown in certain women unable to withstand normal physiological stress. Yet the title is here allowed to stand without change, as it expresses clearly the purpose of this brief article, which attempts to follow the fortunes of those women who suffer from mental symptoms during labour and the puerperium.

Some space must be devoted to clearing the ground and defining the scope of the inquiry. Many patients suffer from mild confusion, depression, or other mental symptom after childbirth, who never have to leave their homes, and who are looked after with varying skill and success by their doctor or nurse. Others are sent to nursing home or observation ward, and return home after a brief stay of a few days or weeks. Others, again, will require treatment in a mental hospital. It is evident that there can be no reliable figures of the whole number of women who develop mental symptoms in the childbearing period, figures that are recorded being mainly concerned with those cases requiring mental hospital care. Such figures vary considerably according to different observers. The variation depends on nomenclature, the type of hospital receiving the patient, and even differences of diagnosis. Notwithstanding these difficulties, there is a considerable agreement which enables broad conclusions to be drawn from available figures. For convenience of description patients suffering from "puerperal insanity" are here divided into two main groups:—

Group I.—This is the larger group and roughly comprises two-thirds of the total cases. In this group the symptoms are due to the occurrence of well-known mental diseases, such as the manic-depressive psychosis, and the wide class of schizophrenic disorders in which dementia præcox, paraphrenia, and a rare paranoia would be included.

Group II.—The remaining third of the total cases consists of two parts, a larger and a smaller. The smaller, not strictly within the scope of this review, is made up of the neuroses and psychoneuroses; hysteria, neurasthenia, obsessional, and anxiety states occurring in connexion with childbirth. The larger part of the group is composed of those patients who exhibit mental symptoms in association with some bodily disorder, the most frequent being puerperal sepsis.

With these two main divisions in mind a more detailed examination of the cases falling into each will be made, together with the factors on which prognosis rests.

Symptoms due to Well-known Mental Diseases

The prognosis in Group I. will depend largely on the diagnosis at which the physician arrives. A striking feature of the mental symptoms of puerperal cases is the predominance of depression.

Very many of the depressive cases will be found to be due to the depressive phase of the *manic-depressive psychosis*. For the most part, the prognosis is good for the individual attack, and a guide to the duration of the illness may be obtained from the history of previous attacks which are likely to have occurred. The ever-present danger of suicide in depression must be remembered, and survival, when marked suicidal propensities are present, can only be ensured by adequate nursing, probably under mental hospital conditions. Prognosis will also depend partly on the number and severity of previous attacks, remembering that successive attacks tend to become longer and the normal intervals shorter. Chronicity is more likely also in those cases with a bad family history. While most of such women make a good recovery for the individual attack, their future is not so satisfactory. Recurrence is probable under a similar stress. It should be the duty of the practitioner to minimise the chances of recurrence. It is wise to insist on two years elapsing before pregnancy is risked again, and then only if the patient has remained mentally and physically well. Another factor affecting the ultimate prognosis of such cases is the well-being or otherwise of the marital and domestic life. Patient and husband must be adequately instructed in suitable contraceptive measures. This type of patient is especially suitable for the measure of voluntary sterilisation, recently proposed in what is known as the Brock report on sterilisation. While a further pregnancy is likely to precipitate another attack, it must not be forgotten that symptoms may well be provoked by uncertainty, anxiety, and worry about a possible pregnancy. As a rough guide the manic-depressive cases may be estimated at from 40 to 50 per cent. of the whole, of which all but 3 to 4 per cent. make good recoveries.

In *schizophrenics*, in contrast to the depressives, the outlook for recovery is poor. Young patients exhibiting catatonic features are, perhaps, the most likely to do well, the rapidly deteriorating personalities being the most hopeless. Figures are not easy to arrive at, but from 15 to 18 per cent. of the total cases may be taken as a fair estimate. Unfortunately, it may be put another way—namely, that of every 100 women who suffer from "puerperal insanity," fifteen or more are likely to become chronic inmates of mental hospitals. Serious schizoid mental symptoms in the puerperal period have therefore an unfavourable prognosis, and there is little more to be said. A strong hereditary strain may be found in the family of the patient, and a careful history of the individual usually reveals to a skilled inquirer undesirable traits of character commencing in childhood.

Psychoneuroses and Neuroses.—The Confusional Psychosis.

As has been said, in Group II. are included a larger number of patients suffering from mental symptoms associated with bodily disorders, and a smaller number of the neuroses and psychoneuroses. Together these conditions account for roughly one-third of the total of puerperal mental states.

The pyschoneuroses and neuroses may be dealt with very briefly. Their symptoms are both mental and physical, and occur later in the puerperium than those of "puerperal insanity." In fact they are most prone to occur when the patient commences to get up and about. These illnesses have a good prognosis if recognised early and carefully treated. Indeed, the prognosis is excellent if the practitioner is able to insist on a return to bed and a prolonged rest. Later the question of psychotherapy may be considered; but rest is the first essential. It must, however, be admitted that hysterical and anxiety symptoms are very liable to recur, and a good prognosis may first require a successful treatment, not of the woman herself, but of her husband and the conditions of her everyday life.

The confusional psychosis, by far the commonest case in this one-third of the total, is that associated with bodily disease. Such disease may be severe hæmorrhage, eclampsia, puerperal sepsis, or even a passing infection acquired during the puerperium—for example, influenza. The mental condition common to them all is what is known as the confusional psychosis, with confusion as its cardinal sign. The confusional state may vary from a delirium accompanying severe and often fatal sepsis, to a restless, confused mental illness persisting for months after the disappearance of the physical condition by which it was initiated. Infection occupies the chief place in the ætiology of this group, and there are authorities who insist that infection, shown by a slight and often overlooked pyrexia, plays a much greater part in "puerperal insanity" than is generally recognised. The prognosis in general is good, provided the patient survives the bodily condition behind the symptoms.

Confusional states associated with eclampsia seem invariably favourable and clear up in two to three months. After severe hæmorrhage and conditions producing profound debility, the confusion is slower to clear and may last for six months or more. With puerperal sepsis the prognosis depends in an especial manner on the physical state. The presence or absence of a blood infection, of peritoneal involvement, of one of the many possible accidents of septicæmia are all matters of grave importance. Mental confusion, associated with serious puerperal sepsis, means a fatal termination to about half the cases. Given survival, the prognosis is good, an average duration being about six months, but the persistence of the symptoms for a year should cause little anxiety as to the ultimate result, very few cases becoming chronic. The confusional patient ought not to break down in a future pregnancy, provided that the health of the mother is completely restored. An interval of two years is a safe rule, as in Group I.

Summary

When this brief discussion of the prognosis in "puerperal insanity" is summarised, the condition is readily appreciated as a serious complication of the puerperium. A vivid presentation of the prognosis may be obtained by following the fates of an average set of 100 mothers who exhibit mental symptoms during the puerperium. In this article the cases have been divided into two descriptive groups. The larger, two-thirds of the whole, consists of patients who develop one of the familiar types of mental disease, such as the manic-depressive psychosis or schizophrenia, pregnancy and parturition acting as a precipitating stress. The second, smaller group, one-third of the whole, is made up of a few neuroses and psychoneuroses, and a larger number of patients showing confusional mental symptoms associated with bodily disorders, of which puerperal sepsis is the most common. About 8 per cent. of the women die, and about 20 per cent. remain chronic mental invalids, whether in or out of mental hospitals. Of the 70 per cent. or thereabouts who recover, many live under the shadow of recurrence, after suffering an illness of some months' duration.

The figures which have been used in this article have been assembled from personal cases and from the works of W. S. Dawson, (1930), A. W. Bourne (1924), E. W. Anderson (1933), Toulouse et Courtois (1932), and G. Clarke (1913), to whom I would express my indebtedness.

SPECIAL ARTICLES

SOME RESULTS OF THE APPLICATION OF A SIMPLE TEST FOR EFFICIENCY OF PASTEURISATION

BY H. D. KAY, O.B.E., Ph.D., D.Sc.
DIRECTOR OF THE NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING, AND RESEARCH PROFESSOR OF BIOCHEMISTRY, UNIVERSITY OF READING; AND
F. K. NEAVE, B.S.A.

As is well known, the meaning of the word "pasteurised" as applied to milk in this country is quite clearly and legally defined and no milk which has not been subjected to the legally defined process may be sold as "pasteurised milk." It is also well known that if the British official stipulations regarding pasteurisation are properly carried out, any pathogenic organisms which are likely to be present in ordinary raw milk are destroyed, and that with a margin of safety. These regulations require that milk, to be pasteurised, shall be "retained at a temperature of not less than 145° and not more than 150° Fahrenheit for at least half an hour, and be immediately cooled to a temperature of not more than 55° Fahr[illegible]" Further, it is required that "the type o[illegible] used for pasteurising and the methods em[illegible] be such as are satisfactory to the licensing [illegible]

Hitherto no satisfactory method has been available for controlling the efficiency of the process by examination of the product, and as a consequence, pasteurisation plants have tended to be assessed more by their appearance and by the claims made for them than by their proven functional excellence. Although, indeed, the experienced licensing authority can satisfy himself by inspection whether some at least of the many possible sources of trouble have been avoided, to judge from inspection alone whether a given machine will produce efficiently pasteurised milk, day in and day out, is obviously impossible. In practice such inspection, if combined with careful bacteriological testing and accurate temperature recording, is usually sufficient to decide whether or not a given plant is functioning satisfactorily. But this is too complicated a procedure for the overworked local authority to conduct frequently; some quicker test, preferably on the pasteurised milk itself without inspection of the plant, would have obvious advantages if it were reasonably simple and certain.

Such a test has, it is believed, been discovered, and it is described in some detail elsewhere.[1] It depends on the finding [2] that phosphatase, an enzyme whose pr[illegible] and quantity can be detected and determi[illegible] and which is present in all raw milk, h[illegible] ly convenient property of being almost [illegible] estroyed by "legal" pasteurisation, but [illegible] completely destroyed if the milk is heated [illegible] han 145° F. or for

Intm. = intermediate. * Slight error in technique. † From vat.

a shorter period than thirty minutes. Thus milk heated at 143·5° for half an hour, or milk heated at 145° for only twenty minutes, or milk containing as little as 0·25 per cent. of raw milk in the properly pasteurised bulk, still contains detectable quantities of the enzyme.

Over all ranges of temperature and time *Mycobacterium tuberculosis* is destroyed rather more quickly than the phosphatase, so that a heated milk which does not contain the enzyme has presumably been sufficiently heated to destroy any *M. tuberculosis* originally present and hence [3] all the common pathogenic organisms. It is naturally not possible by the phosphatase test to decide whether or not there has been infection of the milk *after* pasteurisation, nor is it absolutely certain that in a milk which gives a negative phosphatase test every pathogenic organism has been destroyed—i.e., it is possible to imagine a small leak of raw, infected milk into the pasteurised bulk, after heating, in insufficient quantities to give a positive phosphatase test but in sufficient amounts to convey infection.

Observations on "Pasteurised" Milks

The purpose of this communication is not to discuss the test in detail, but to give some recent representative results, which have been obtained by applying the test to milk, sold to the public or sold to school-children under the "milk in schools" scheme, *as designated "pasteurised,"* in two London boroughs, five provincial towns, and in certain rural districts. The samples have been bought over the counter, or taken from consignments being sent for sale in schools by arrangement with the local authority, or collected by the official representatives of local authorities, without any selection of better or poorer distributors.

The figures shown in the accompanying Table as "blue units" have a quantitative significance, which may be interpreted as follows: below 2·3 units the milk has been heated at such a temperature and for such a length of time as to destroy pathogenic organisms; between 2·3 and 6 units there has been some error in the pasteurisation technique; above 6 units there has been some gross error in the pasteurisation technique; above 10 units not only is the error in technique gross, but the milk may, in fact, never have been heated at all.

In the case of milks which the test shows to be in the category "incorrectly pasteurised," though there is no doubt that correct "legal" pasteurisation has not been carried out, the error is not very great and it is likely that a slight tightening-up of the technique, or small alterations or readjustment in the apparatus will enable a more satisfactory product to be turned out. On the other hand, in cases where the milk is found to be "grossly underheated," there is either serious inefficiency of the plant, carelessness in management, or fraud.

Comment

On the whole, the data speak for themselves and comment at this stage will be limited to a few lines. From the figures published above, and from a large number of others in our possession, it seems to us that our recent application of the phosphatase test permits the following statements:—

(1) A large number of pasteurising plants of all sizes both in London and elsewhere are either inherently functionally inefficient or unsatisfactorily operated.

(2) The properly designed and supervised plants, whether large or small, provide a satisfactory product. The phosphatase test has proved a valuable aid in this supervision.

(3) Of the large firms a majority, but by no means all, use efficient plants and/or methods.

(4) The milk sold to school-children as "pasteurised" appears, in a large proportion of the cases examined, to have been pasteurised in a particularly amateurish way.

(5) In view of the large percentage of designated "pasteurised" milks on the market which have been grossly underheated it is particularly desirable that all milk, and especially milk which is to be consumed by school-children, should reach a reasonable hygienic standard — say, Grade A — before pasteurisation.

We are indebted to Dr. H. J. Milligan (Reading), Dr. William Stott (Southwark), Dr. W. R. Graham, Mr. T. H. Jenks (Aylesbury), Mr. J. McClemont, and Mr. W. A. Hoy for their help during the course of this work.

MEDICINE AND THE LAW

Fees of Doctors called in by Midwives

IN Brown and others *v.* Monmouthshire County Council (see THE LANCET, March 23rd, 1935, p. 694) the Court of Appeal held ultra vires paragraph 8 of a scale of fees fixed by the Ministry of Health in 1922 under Section 14 of the Midwives Act of 1918 where a midwife calls in a registered medical practitioner in emergency. The county council could have appealed against this decision and the Ministry, whose order was successfully impugned, might have been interested in the fighting of his battle. The Minister has, however, intimated to local supervising authorities that there will be no appeal, and that his prescribed scale of fees is to be read as if the offending paragraph 8 were deleted. Doctors' fees for services when called in by midwives in emergency are therefore now governed by the first seven paragraphs of the scale, although the Minister states that he is considering the question of amending Section 14. In the Court of Appeal the Master of the Rolls observed that the keynote of the Midwives Acts of 1902 and 1918 was that it is to the interest of the State that a mother and her child shall be so treated in the matter of child-bearing that the mother shall not be injured but shall be restored to health, and that the child shall not suffer disability. The power of the midwife to call in a registered practitioner in emergency, he added, carries out this important principle of the Acts. Section 14 said that in such cases the local authority should pay the practitioner "a sufficient fee, with due allowance for mileage" according to the scale fixed by the department. The scale fixed in 1922 set forth seven items. The first was a fee for all attendances of a doctor at parturition, the second a fee for a second doctor attending to give an anæsthetic, the third a fee for suturing the perineum, and so on up to the seventh, which was a fee for attendance on mother and child at the doctor's residence or surgery. Then came paragraph 8, which said that in particular circumstances specified—e.g., where the doctor attends under club arrangements—no fee at all should be payable. In the cases which came before the Court of Appeal last March it was agreed on all sides that the doctors had been properly called in by midwives in emergency; they were therefore entitled under the Act to their "sufficient fee with due allowance for mileage." When the county council took refuge under paragraph 8, the Court of Appeal in effect declared that a power to fix fees (under Section 14) was not a power to deprive doctors of fees, or as Lord Justice Romer put it, a power to fix a general scale universally applicable to all practitioners was not a power to discriminate between one practitioner and another. If the Minister is to be able to prescribe the conditions for withholding fees under Section 14, or for discriminating between doctors in different cases, he must show the statutory authority under which he purports to act. He could produce no such authority to the Court of Appeal, but the intimation in his circular suggests that he may presently ask Parliament to give him the authority he now lacks. His proposals should be carefully scrutinised.

The matter can stand on the broad principle enunciated by the Master of the Rolls. The country wants the best possible treatment for mother and child in emergency cases of childbirth. Parliament has said that the doctors shall have a sufficient fee—a not unreasonable element in any scheme for obtaining the best possible treatment. Local authorities have readily recognised the doctor's statutory right to his fee under Section 14; the Monmouthshire County Council itself is believed to have paid such fees without hesitation until it began to take refuge behind paragraph 8 which the courts have ruled to be invalid. It is not in the interests of a satisfactory midwifery service that doctors should be allowed to feel that a local authority wants to wriggle out of a statutory obligation.

Proposed Changes in Coroners' Law

Last week a coroner complained that the police were duplicating the work of preliminary investigation which his officer had in hand. The incident is a reminder of the indefinite and unrecognised position of the coroner's officer, of whom the Coroners Acts make no mention. The Departmental Committee on Coroners' Law and Practice has had its attention drawn to this point by a recent memorandum submitted on behalf of the British Medical Association. The memorandum advocates statutory recognition of the coroner's officer and specific provision that he shall in all cases be a police officer. Other matters mentioned by the Association's memorandum include a reference to the increasing practice of coroners in seeking to obtain (often through the coroner's officer or a police officer) information from the medical attendant of the deceased as to his medical history. The memorandum rightly deprecates this attempt to obtain medical evidence through a third person. Though the Acts make no special provision for a fee for a doctor's report in such cases, some local authorities use their discretionary power to pay a fee of 10*s.* 6*d.* (or in some cases £1 1*s.*), while others refuse to make any payment. There can be little doubt that the medical attendant's report is of value in the economic administration of justice and in the public interest. It seems entirely reasonable to recommend statutory provision for a fee not less than 10*s.* 6*d.*

The memorandum usefully reminds the committee that the Acts make no provision for travelling expenses where the practitioner attends to give evidence at an inquest. He may often be required to travel a considerable distance, and it would be equitable that the law should be amended to authorise a mileage fee which some county councils already allow. Another suggestion to the committee concerns the presence at post-mortem examinations of the practitioner who has been attending the deceased in his lifetime. Section 22 of the 1926 Act enables the coroner to request any duly qualified practitioner (whether the deceased's medical attendant or not) to make the examination; he can also ask some specially qualified person to make a special examination. Coroners are making, quite properly, an increasing use of this latter power. Without wishing to restrict their discretion in this respect, the British Medical Association wants to safeguard the position of the deceased's medical attendant by (*a*) allowing him to be present at the autopsy (without statutory fee) where he does not himself conduct it, and (*b*) giving the coroner a statutory discretion to invite the deceased's medical attendant to be present at the post-mortem examination at a statutory fee of £1 1*s.*

Other points in the Association's memorandum must be briefly mentioned. It would place the coroner and his procedure and practice more effectively under the control of the Lord Chancellor; it would require coroners to preserve their official records; and it would leave the viewing of the body, at present obligatory upon the coroner and discretionary or optional for the jury under Section 14 of the 1926 Act, to be optional for the coroner also. It would encourage the coroner to dispense with an inquest where death occurs after surgical operation before complete recovery from the anæsthetic, in any case where both the coroner and the relatives are satisfied after proper opportunities of inquiry that there was no neglect. The Association would similarly enlarge the coroner's discretion to dispense with an inquest in certain cases where, though at present required by Section 3 (1) of the 1887 Act to investigate because there is reasonable cause to suspect violent or unnatural death, he is nevertheless himself satisfied that the case is free from suspicion and that the holding of an inquest will serve no useful purpose. Here the Association has in mind the type of case where a person of advanced age dies from injury or where death occurs from bacterial food poisoning when there is no suspicion or element of doubt as to the cause of death. Finally, the Association suggests that statutory protection should be given to the medical practitioners on whose conduct comment has been made during an inquest. The practitioner, it is suggested, should have a right to offer rebutting evidence, to be legally represented if he so desires, and to have an adjournment of the inquest for this purpose. The normal exercise of the judicial function should secure this measure of fair play, and possibly Parliament will be reluctant to tie the coroner's hands.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

SPECIAL SCHOOLS

THE needs and the faults of special schools were emphasised at the sixteenth biennial conference of the National Special Schools Union held in Edinburgh last week. Dr. G. J. Linklater, school medical officer for the city of Edinburgh, emphasised the great need for an institution in which rheumatic children could be given adequate rest and also educated; it is impossible for them, as he said, to get proper rest in working-class homes. Prof. Drever, of the chair of psychology, severely criticised the special school for mental defectives on the ground that segregation under medical certification of children a fair proportion of whom were capable of becoming self-supporting citizens could not be justified from a social point of view. The use of the term "mentally defective" was an initial mistake, and its effects were not going to be easily eradicated. Miss C. R. Grant and Dr. Douglas Guthrie referring to speech disturbances, emphasised the importance of coöperation between the teacher and the speech clinic.

THE SHARPEY SCHAFER LECTURESHIP

The Sharpey Schafer lectureship in physiology in the University of Edinburgh was formally inaugurated last week when Sir Charles Sherrington lectured on Sir Edward Sharpey Schafer and his contributions to neurology. The prosperity of physiology was one of Sir Edward's most cherished aims. He had an exceptionally wide outlook on his subject and his published contributions ranged over subjects so diverse as the origin of life, the migration of birds, the endocrine organs, the cortex of the brain, and the pulmonary circulation. His early work on the endocrine glands has proved to be of the greatest importance, and his investigations of the cerebral cortex were also most significant.

LEWIS CAMERON FUND

The first appointment under the scheme recently approved by the court of session for the administration of the Lewis Cameron Fund has been announced at a meeting of the university court of the University of Edinburgh. Mr. C. G. Anderson, Ph.D., has been appointed Lewis Cameron teaching fellow in the department of bacteriology. Mr. Anderson, who is a graduate of the University of Birmingham, is at present a member of the teaching staff of the London School of Hygiene and Tropical Medicine.

PARIS

(FROM OUR OWN CORRESPONDENT)

THE QUALITY OF FRENCH BREAD

BREAD being to a Frenchman what the potato is to an Irishman, it is astonishing that he has never yet made violent protest against the execrable concoction which looks like a loaf and acts like a brick-bat inside him. Before the war there was nothing to complain of, unless it were that wholemeal bread was difficult to obtain. And as it was demanded only by a small group of food faddists, the failure of French bakers to produce it did not matter. The war, however, brought revolution to the daily bread. Rice, maize, barley, and other substitutes for wheat figures in various proportions in the loaf which, when at last it reached the consumer, was so small that the possibilities of further diminution put thoughts of quality out of his mind. Ever since the war, the French have been asking themselves with growing querulousness why their bread has been getting worse and worse instead of better and better. There is a glut of wheat which should render substitutes superfluous. But what is probably an even more serious matter than the surreptitious employment of wheat substitutes is the modern baking technique which suits the convenience of bakers rather than the stomachs of consumers. Opinion has now become so strong that an appeal has been made to the Academy of Medicine in the hope that this august body will find a way back to the palatable and digestible pre-war loaf. In a recent communication to the Academy, Dr. Henri Labbé made the startling statement that things had come to such a pass that Frenchmen eat about 20 per cent., less bread than they used to. Among the needful reforms—apart from the disuse of substitutes—he places in the first rank a return to yeast and the rather leisurely procedures which its employment entails. It may be that ferments derived from molasses accelerate the processes of baking and require less skill and patience, but they yield a loaf lacking the palatability which one is justified in asking. The ideal fuel for baking he says is wood. Gas and electricity come next. Last, and easily the worst, is the mazout, or crude oil preparation, whose comparative cheapness has been the cause of its ousting wood. Dr. Labbé considers *mazout* such an important cause of the badness of the present-day loaf that he would like this fuel to be prohibited for baking. He concluded with a tilt against the abolition of night baking. It has, in his opinion, prompted expedients, short-cuts, and technical compromises which have seriously impaired the loaf's intrinsic value. How to give the baker sleep and his customer a good digestion? Dr. Labbé's answer is the central bakery, large enough to be staffed with three teams each of which works for eight hours. A continuous 24-hour cycle would thus be created and, let us hope, "the bread will again become the healthy, economic, savoury, digestive and energetic food to which our fellow-countrymen are accustomed by tradition."

SHOULD DOCTORS STARVE IN TOWN OR COUNTRY?

Correspondence in *Concours Médical* has enabled various writers to express their views on the present distressing plethora in the medical profession. One of them has exposed a fallacy which, he fears, may not be recognised as such by earnest young men lacking discernment. They are being told that in Paris there is one doctor to every 600 inhabitants, whereas in certain country districts there is hardly one doctor to every 3000 inhabitants. The unwary may be tempted to conclude from this comparison that their chances of making a living will be five times greater in the country than in a town. One correspondent has put the matter in a nutshell. "All who discuss the plethora neglect an enormous factor—the wealth of the inhabitants. One doctor for 600 or for 5000 inhabitants—that means nothing. It is statistics, it is a lie. It is not the inhabitants who enable the doctor to live, it is not even merely the patients, but only those who take care of themselves. To take care of yourself, you must have money; and the whole crux of the matter is there." In other words, it behoves the would-be medical settler in a new district to count incomes, not heads. A rough-and-ready way of such counting is to note the number of jewellers in the area in question. Another is to visit its cemetery and see if its monuments are costly and well preserved or not. There is a third way, but it leads nowhere. It is to note where other doctors are most and least numerous.

STOCKPORT INFIRMARY.—A new block is to be erected at Stockport Infirmary at an estimated cost of £35,000. It is to include two operating theatres, two wards of 24 beds each, and a lower ground floor providing further accommodation.

HOSPITAL AND PRACTITIONER

AN ADDRESS BY DR. COX

IN opening extensions at the Wilson Hospital, Mitcham, last Saturday, Dr. Alfred Cox, late medical Secretary of the British Medical Association, made some cogent comments on the relationship of hospitals to private practitioners. He pointed out that the recognition of the hospital as a part of communal life, in which the man in the street ought to take an interest, was a comparatively recent thing. There had been hospitals of course for centuries, but only in the last fifty or sixty years had they been regarded as essentials. "When I was a young man," said Dr. Cox, "practically everything in the provision of health was done by the family doctor. There were few consultants, and very few medical officers of health or sanitary officials; hospitals were few and centralised, and to go to hospital was regarded by most people as the very last resort, and often as equivalent to a death sentence. Nowadays the health service is recognised to be a *team* composed of medical officer of health, family doctor, consultant, hospital and many auxiliary services. It is as impossible to say which is the most important member of the team as it is to say which leg of a three-legged stool is the most important. But I believe that, to change the metaphor, the family doctor is the keystone of the building. It is necessary to say this because these are the days of 'publicity,' and the work done at hospitals is so much more sensational and dramatic that the quiet day-to-day work of the family doctor is in danger of being overlooked. He makes no appeal in the newspapers and gets no limelight. But without him the hospital and the specialist would be far less useful than they are."

"I reckon," continued Dr. Cox "that a patient who can be seen in consultation by his family doctor and the surgeon who is going to operate, starts his operation with at least a 20 per cent. advantage. And remember that for once that a person needs to go into hospital he is likely to need his family doctor ten times. With a long experience, both as a general practitioner and as an organiser of the medical profession, I say that a family which has a reliable and trusted home doctor are much less likely to require hospital treatment than one which has no such adviser, and when they do require it are likely to get more benefit from it. . ."

"Most doctors in the big towns, and indeed over large parts of the country, have no direct connexion with a hospital, whereas if they are to be as useful as they should be to the public as family doctors, the connexion cannot be too close. . . Every doctor will tell you that the doctor who has the luck to be on the staff of a hospital has great advantages, because the hospital is the very centre and spring of all medical knowledge. Books, medical meetings, lectures are all very well in their way, but nothing can take the place of the hospital. There the doctor can use many methods of treatment which cannot be carried out at his surgery or in his patients' homes; there he is in contact with his colleagues and nothing is so likely to keep him up to the mark; there he is under the critical observation of the nurse, who is a very good judge of what a doctor should be; and there he can get the advice of specialists who are at his call when required. I wish every district in this country could follow the example of Mitcham and provide for its doctors a place in which their education could be continued, in the only place that it *can* be carried on properly—namely in a hospital. And obviously the knowledge and skill they acquire there is available in their daily work for people who may never see the inside of a hospital."

Turning to the proper use of out-patient departments Dr. Cox said there were three purposes for which such departments could be legitimately used: (1) for accidents and emergencies; (2) for special examinations and forms of treatment which cannot be done well, or cannot be done at all, at home or in the doctor's surgery; (3) for consultation purposes where the family doctor wants further advice. About the first two objects there was no difference of opinion, but unfortunately many hospitals deliberately encouraged the use of their out-patient departments so that in appealing for subscriptions they might boast about the large numbers of out-patients—whereas they ought to be ashamed of them. "It is like using a steam hammer to crack a nut, to use a hospital for such purposes, and a shocking waste of the subscribers' money and the doctors' time. Why should hospitals encourage people to apply for charity when the thing they need can quite well be supplied at their own cost? If they find difficulty in paying doctors' bills they can, in any part of London, and in most large centres now, get the doctor of their own choice without any suspicion of charity, through the public medical service which provides them with a family doctor on easy terms, and if the doctor thinks they need to go to hospital he will send them there with a statement about their case which will greatly help the consultant in giving his opinion.

"Moreover, the out-patient department which does what I am complaining about has a very bad effect on the doctors who have to live by their practices which the out-patient departments are poaching from them. These doctors, finding much of their work being filched from them by the very institutions often which have trained them, naturally become less interested in their profession, less experienced in their practice, and therefore less useful to the public they are supposed to serve. . .

"The medical service of the future ought to have as its object to prevent as much sickness as possible, to catch cases that do arise as early as possible, and to treat those who fall ill with every available means. It could be done easily enough by a form of insurance to which all but the really well-off should contribute. There should be no charity about it either inside or outside the hospital. I venture to say that for a mere fraction of the amount now spent on cinemas, dancing, beauty preparations, and wireless apparatus, every member of the public could be given a first-class health service. It's a curious thing, however, that after long years of compulsory education an idea of this kind should be regarded as utopian. To most people the pleasures of life are vastly more important than its necessities, and people who would scorn the mention of charity as regards their food and clothing think it quite natural to apply for it in connexion with their health. I am particularly glad to find that in this hospital people are expected to pay according to their means. Charity is a blessed thing, but it is not as important as the cultivation of self-respect and independence."

ALEXANDRA HOSPITAL FOR CHILDREN, SWANLEY.—Lady Cornwallis has opened a new nurses' home at this institution. It has cost £20,000 and has accommodation for 40 nurses.

PANEL AND CONTRACT PRACTICE

In the Matter of Fee-charging

It is quite a common occurrence in insurance practice for a patient who has been treated privately to apply later for the withdrawal of the account or for a refund of fees paid. Under Clause 7 (3) of the Terms of Service if a person in applying for treatment does not represent himself to be an insured person, but subsequently ("within one month from the date of the presentation by the practitioner of an account or the payment to the practitioner of any fee or the last of any fees paid, where no account is rendered, in respect of that treatment") requests the insurance committee to secure the withdrawal of the account or the refund of the fee(s) and the committee are satisfied that he was eligible to receive treatment from the practitioner as an insured person, the committee may, if they think fit, require the practitioner to withdraw his account or recover from him the fee(s) paid by the applicant. In either event they must credit the practitioner with the remuneration to which he would have been entitled if the applicant had been attended by him as a temporary resident and with payments calculated on the basis of the drug tariff in respect of any drugs and prescribed appliances supplied to the applicant. In the event of their allowing the insured person's application the committee have power to inflict a penalty not exceeding *2s. 6d.* Cases of this type cause much misunderstanding and frequently annoyance to the practitioner concerned, and it may be by no means easy for an insurance committee to determine whether the applicant was eligible to receive treatment from the practitioner as an insured person. It may be useful to cite briefly some cases recently reported to insurance committees in three of which the committee decided that the application should not be granted.

(1) A.B. when applying for treatment made no representation of his title to benefit under the Acts, and in reply to an inquiry from the committee the doctor stated that Clause 7 (3) would not, in his opinion, meet the case as he was dealing with well-to-do people who could well afford reasonable fees. It was pointed out to the doctor that these circumstances could in no way affect the obligations accepted by him in his agreement with the committee, and as the person was entitled to receive medical benefit he could not be deprived of the rights which the Acts confer. Under the terms of service a doctor is not permitted to demand or accept any fee or other remuneration in respect of treatment required to be given thereunder except the remuneration to which he is entitled from the insurance committee. The doctor then furnished the committee with a statement signed by the insured person to the effect that he did not expect to receive treatment under the insurance scheme but that he wished to be treated as a private patient and to pay the doctor his normal fees. Even a horse led to the trough cannot be compelled to drink and the committee decided that the application for refund should be disallowed.

(2) C.D. on marriage removed from the area of the insurance committee but was advised by her approved society of the benefits to which she was entitled as a married woman. Returning temporarily to her former home in the committee's area she required medical treatment while there. The doctor called inquired if she was entitled to medical benefit and, being informed by her that she was not, he treated her privately. Her husband consulted the committee, and was informed that, having regard to the wife's statement to the doctor, the committee had no power to call upon him to withdraw his account. The woman who gives up work on marriage provides a large proportion of cases which require to be dealt with under Clause 7 (3). She is apt to think that, as she is no longer entitled to the ordinary benefits of an employed contributor, her title to medical benefit has also ceased. Later she learns that medical benefit continues for a period after cessation of employment and then endeavours to secure repayment of the money paid to the doctor. Broadly speaking, the position of a woman employed up to the time of her marriage is that medical benefit continues until June 30th or Dec. 31st, whichever first occurs after the expiration of a year from the end of the eighth consecutive week of unemployment.

(3) E.F. was taken ill in the night and an insurance doctor, other than the one in whose list E.F.'s name was included, was called to give treatment. The doctor who attended was informed that E.F.'s own doctor was not called as he was too far away and in these circumstances it was suggested that the patient should transfer. No steps were however taken to do this until a week later. The doctor stated he was not prepared to submit a claim for treatment given in case of accident or other sudden emergency as there was, in his opinion, a growing feeling amongst insurance patients that they could call in any doctor they wished at any time and he considered that this was a typical case. The committee were not satisfied that there were reasonable grounds for failing to call in the insurance doctor responsible for the patient's treatment and the application failed. There is often an honest difference of opinion as to what constitutes an emergency. In the mind of the patient and his relatives there may be emergency, while the examining practitioner may form a contrary opinion. The patient can hardly be expected to differentiate abdominal pain caused by indigestion from the symptoms of appendicitis, and committees find it difficult to determine whether an emergency existed or not. If the insured person's own doctor is summoned and the call proves unnecessary the practitioner may feel annoyed but the patient is relieved of anxiety. If however the responsible practitioner lives at some distance and the "nearest doctor" is called in he may consider that medically there was no emergency and be disinclined to submit an application for payment as though it were. Yet if he charges the patient he is taking from the insurance and the panel committee the right to determine whether the patient was eligible to receive treatment from him as an insured person. If therefore the doctor who is summoned wishes to claim a fee for his attendance he will be well advised, when made aware that the patient is an insured person, to claim on the appropriate form and leave it to the committee to decide whether there was an emergency or not. The Ministry have advised a panel committee that in cases of this type their tendency should be in the direction of giving the patient the benefit of any doubt.

(4) G.H., an insured person, was on the list of Dr. A. but obtained treatment from his partner, Dr. B., under the impression that Dr. B. would undertake responsibility as deputy for Dr. A., Dr. B.'s surgery being open on the only evening in the week upon which she was able to consult the doctor. After attending Dr. B. for a special form of treatment by arrangement with Dr. A. she subsequently consulted Dr. B. upon another matter when he took the attitude that he was not responsible for her treatment and referred her to his partner. Arrangement was then made between them for the patient to be treated privately for which an account in the name of the partnership was rendered. An officer of the committee interviewed the patient and both doctors with the result that the account was cancelled and Dr. A. gave consent to the transfer of the patient to the list of another doctor. Although the insured person stated that the question raised by her had been satisfactorily adjusted, the committee felt it necessary from the point of view of general administration to call the attention of both doctors to the obligations accepted by them under their terms of service regarding deputies and partners. Clause 11 (8) provides in the case of two or more practitioners practising in partnership that treatment may at any time be given by a partner of the practitioner in whose list the patient is included, instead of by the practitioner in person,

provided that reasonable steps are taken to secure continuity of treatment. In the case of a partnership the patient cannot demand that treatment shall be provided by the doctor by whom he has secured acceptance, as he can in the case of principal and assistant.

An American Plebiscite

The introduction of compulsory health insurance into the United States is now being much discussed by dentists as well as doctors, and *Oral Hygiene*, an American dental journal, has lately tried to ascertain what views are held by the dental profession as a whole. The issue has become pressing, it is felt, because of the reduction in incomes from private practice.

To a questionnaire circulated last January replies were received from 5846 dentists, forming rather more than 9 per cent. of the number registered—which it appears is a high proportion of voters for an American journalistic poll. It is stated that the poll was taken in a serious spirit by those participating, for "flippant and scurrilous remarks or the comments of cranks and crack-pots were made on only five ballots." Analysis shows that the principle of health insurance was approved by 4513 votes against 1294, and on the question whether dental care should be included as a statutory or an additional benefit, the inclusion as a statutory benefit was supported by 4432 votes against 56. There was a consensus of opinion that the application of a health insurance scheme should be restricted to persons with a family income not exceeding $1500 (£300). Replies were also invited on the questions whether the dental services provided under health insurance should be "limited" or "adequate," and whether they should be confined to wage-earners only or be extended to the members of their families. An "adequate" service was approved by 3232 votes to 1138, and extension to the families by 3936 to 274. A considerable number of voters supplemented their answers to the questions by expressions of opinion on various other points. Many of them thought that immediate action was necessary to "bring the producer and consumer of medical and dental services together," but some, though they favoured the principle of health insurance, feared that it might lead to "political domination and control." By some voters it was thought that health insurance would eliminate the advertising dentist.

The results of the poll suggest a remarkable change of view in American dental circles; it is highly improbable that so high a proportion of votes would have been cast in favour of health insurance a few years ago. A similar attempt to ascertain the views of the medical profession in America might yield interesting results. Such a poll affords an opportunity for expressions of opinion from the rank and file, many of whom, though not prominent at meetings or in the correspondence columns of professional journals, have formed definite views and are prepared to act on them at the appropriate time.

School Medical Records

It has long been felt that the value of the forms of medical record relating to insured persons would be increased if the records of treatment during school life could be made available for incorporation therein. A subcommittee of the London County Council's education committee has been considering a resolution from the London Teachers Association urging, first, that school medical record cards should be transferred to the National Health Insurance doctor concerned as soon as a child enters insurance employment, and, secondly, that clinics should be established throughout London where young people of 14 to 18 may obtain free medical advice. The subcommittee informed the Association of the experiment approved by the Council on Feb. 6th, 1934, and April 9th, 1935, for the medical inspection and treatment of students under 16 attending day continuation schools and certain evening institutes, and of the arrangements for the medical inspection of young persons of 14 to 18 years of age attending junior instruction centres. The suggestions in the resolution cover an appreciably wider field than that contemplated in the experiment, but the education committee is not prepared to recommend any further development pending consideration of the results of what is already being tried. Meanwhile it was made clear that there is no objection to the transfer of school medical record cards to panel doctors if they apply for them, and it is to be hoped that wide publicity will be given to this useful concession.

THE SERVICES

INDIAN MEDICAL SERVICE: ANNUAL DINNER

One hundred and seventeen officers of the Indian Medical Service dined together on June 19th at the Trocadero, when Major-General E. A. Walker, C.B., K.H.S., director of medical services in India, presided. The attendance was larger than last year which was itself a record. The members of the Service present were as follows:—

Major-Generals: W. V. Coppinger, C.I.E., D.S.O.; H. Boulton, C.B., C.B.E.; B. H. Deare, C.I.E.; W. C. H. Forster, C.I.E.; Sir John Megaw, K.C.I.E.; C. W. F. Melville, C.B., K.H.P.; Sir Leonard Rogers, K.C.S.I., C.I.E., F.R.S.; and G. Tate, C.I.E.

Colonels: H. Ainsworth; J. Anderson, C.I.E.; J. Crimmin, V.C., C.B., C.I.E.; P. Dee; A. B. Fry, C.B., C.I.E., D.S.O.; T. A. Granger, C.M.G.; C. R. M. Green; E. C. Hodgson, D.S.O., K.H.P.; W. H. Leonard, C.B.; H. M. Mackenzie, C.I.E.; F. P. Mackie, C.S.I., O.B.E.; Sir Richard Needham, C.I.E., D.S.O.; A. H. Proctor, D.S.O.; Ashton Street; H. H. Thorburn, C.I.E.; R. G. Turner, C.M.G., D.S.O.; J. Norman Walker, C.I.E.; N. M. Wilson, O.B.E.; and C. N. C. Wimberley, C.M.G.

Lieut.-Colonels: H. W. Acton, C.I.E.; A. C. Anderson; F. J. Anderson, M.C.; L. A. P. Anderson; S. Anderson; C. H. Barber, D.S.O.; A. N. Bose, M.B.E.; R. H. Bott, C.I.E.; N. Briggs; H. H. Broome, C.I.E.; R. N. Chopra; H. P. Cook; A. G. Coullie; D. G. Crawford; J. M. Crawford, O.B.E.; J. B. Dalzell Hunter, O.B.E.; C. D. Dawes; J. C. De; A. Macdonald Dick, O.B.E.; H. R. Dutton, C.I.E.; S. C. Evans; C. H. Fielding; J. K. S. Fleming, C.B.E.; E. S. Goss, M.C.; G. F. Graham; V. B. Green-Armytage; F. Griffith; A. E. Grisewood; A. F. Hamilton, C.I.E.; W. G. Hamilton; W. L. Harnet, C.I.E.; H. Hingston; J. M. Holmes; T. A. Hughes; E. V. Hugo, C.M.G.; M. L. C. Irvine; S. P. James, C.M.G., F.R.S.; I. Davenport Jones; R. N. Khosla; J. B. Lapsley, M.C.; J. C. H. Leicester, C.I.E.; A. C. Macrae; E. C. G. Maddock, C.I.E.; J. S. S. Martin; W. A. Mearns; T. R. Mulroney; B. E. M. Newland; F. O'Kinealy, C.I.E., C.V.O.; E. J. O'Meara, O.B.E.; E. S. Phipson, D.S.O.; H. Ross, C.I.E., O.B.E.; J. D. Sandes; R. B. S. Sewell, C.I.E.; M. Anup Singh; H. B. Steen; R. Steen; W. A. Sykes, D.S.O.; A. N. Thomas, D.S.O.; C. Thomson; E. Owen Thurston; R. S. Townsend, M.C.; E. L. Ward, C.B.E.; E. E. Waters; W. L. Watson, O.B.E.; and J. D. R. Webb, O.B.E.

Majors: P. M. Antia; S. L. Bhatia, M.C.; H. C.

Brown, C.I.E.; J. Carrey; J. A. Cruickshank, M.C.; Hari Das; P. A. C. Davenport; J. E. Dhunjibhoy; Sir T. Carey Evans, M.C.; W. L. Forsyth; N. H. Hume; D. V. O'Malley, O.B.E.; C. G. Seymour; and F. Norman White, C.I.E.

Captains: J. H. Boultbee; H. J. Curran; A. V. O'Brien; and Jaswant Singh.

Officers on probation: Capt. E. C. Hicks; Lieut. J. Duffy; Lieut. J. T. Franklen-Evans; Lieut. J. Reidy; Lieut. A. W. Sampey; and Lieut. G. C. Welpley.

The last six mentioned were present by invitation, and the other guests were Lieut.-General Sir James Hartigan, K.C.B., C.M.G. (director-general of Army Medical Services), Prof. F. R. Fraser, Mr. W. D. Tomkins (of the India Office), Dr. N. G. Horner (*British Medical Journal*), and Dr. Egbert Morland (*The Lancet*).

After giving the loyal toast, General Walker read a congratulatory telegram from the director-general (Major-General C. A. Sprawson) and officers in India, and proposed "The Service." Previous chairmen of that dinner had, he said, referred mostly to the past. "For myself," he added, "I feel the Service has a future. The day of the I.M.S. is not over. Any organisation possessing the power of adapting itself to changing circumstances which the I.M.S. has always shown is secure." In the future the military element in the Service would be a large one. In 1916 his capture by the Turks in Mesopotamia had given him time to think out Service problems; since then conditions had vastly improved in spite of cuts and financial depression, owing largely to Colonel Alister McNeill, I.M.S., and Colonel Rees Williams, I.M.S. He ended by remarking that the Service was now getting a very high class of recruit.

Sir Leonard Rogers, proposing "The Chairman," recalled his distinction on the civil side in Rangoon before he reached his present position on the military side. He agreed with his estimate of the growing importance of the military branch, while satisfied that the civil branch also had its future. He congratulated Sir James Hartigan on his recent honour and on the cordial relations existing between the R.A.M.C. and the I.M.S. in India.

There were no other speeches, but Colonel Anderson, who has attended every annual dinner and is now within sight of his eightieth birthday, was induced to tell some stories. The staff work of the dinner secretaries was tacitly acknowledged.

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdrs. R. P. Ninnis to *Victory* for Portsmouth Dockyard, and J. D. Bangay to *Cardiff*.

Surg. Comdr. L. A. Moncrieff placed on the Retd. List, at own request, with rank of Surg. Capt.

Surg. Lt.-Comdrs. W. P. E. McIntyre to *Pembroke* for R.N.B., G. A. Miller to *Hermes*, and C. Keating to *President* for course.

Surg. Lt. G. D. Wedd to *Amphion* and to *Victory* for R.N. Hospl., Haslar.

APPOINTMENTS

It is announced that there will be nine vacancies in September, 1935, for Medical Officers in the Royal Naval Medical Service. Candidates must not be above the age of 28 years. No examination in professional subjects will be held, but candidates will be required to attend for interview by a Selection Board. Copies of the regulations may be obtained from the Medical Director-General of the Navy, Admiralty, S.W.1, and from the Deans of all Medical Schools. Applications for entry must be received not later than July 31st.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Capts. L. S. Ashcroft to *Valiant* and J. B. Ronaldson to *Renown*.

Surg. Comdrs. L. C. D. Irvine to *Nelson*, T. W. Drummond to *Curacoa*, W. C. Macartney to *Vindictive*, F. L. Cassidi to *Hawkins*, and S. W. Davidson to *Calypso*.

Surg. Lt.-Comdrs. G. A. Mason, J. B. Hutchinson, and A. S. Bradlaw to *Drake* for R.N.B., and to *Ramillies*; S. B. Borthwick to *Pembroke* for R.N.B., and to *Victory* for Haslar Hospl.; W. P. Elford to *Pembroke* and to *Excellent*; St. G. B. D. Gray to *Broke*; G. McCoull to *Montrose*; F. E. Stabler to *Campbell*; R. Wear, L. D. Nelson, R. J. Matthews, and H. M. Willoughby to *Victory* for R.N.B.; A. H. Shellswell to *Effingham*; T. G. Evans to *Vernon*; B. W. C. Archer to *Vivien*; F. T. Doleman to *Pangbourne*; and A. L. Gunn to *Pembroke* for R.N.B.

Surg. Lt.-Comdr. (D.) E. D. Collins to *Victory* for R.N.B.

Surg. Lts. C. Mason, G. F. S. Parker, and R. D. Bradshaw promoted to Surg. Lt.-Comdrs.

Surg. Lts. G. H. C. R. Critien to *Rodney*; C. A. Mather to *Pembroke* for R.N.B., and to *Shropshire*; D. W. Bawtree to *Drake* for R.N.B., and to *St. Vincent*; W. H. Roberts to *Pangbourne*, R. S. Rudland to *Vivien*, D. Simpson to *Montrose*, E. F. St. J. Lyburn to *Campbell*, R. G. Reid to *Rodney*, A. B. Concanon (proby.) to *Pegasus*, and W. G. Campbell (proby.) to *Shropshire*.

Surg. Lts. (D.) A. C. Fuller (proby.) to *Pembroke* for R.N.B., and to *Rodney*; C. E. Brittan to *Drake* and to *Victory* for R.N. Hospl., Haslar; and A. B. Bateman to *Rodney*.

Proby. Surg. Lt. N. A. Vernon to *Leander*.

Proby. Surg. Lt. G. E. M. Benson to be Surg. Lt.

Proby. Surg. Sub-Lt. R. T. Gaunt to be Surg. Sub-Lt.

Proby. Surg. Sub-Lts. R. T. May to *Nelson*, J. A. Shepherd and D. S. Macphail to *Barham*, D. M. Edwards to *Rodney*, W. H. Osborn and J. B. W. Hayward to *London*, R. F. B. Bennett and P. H. K. Gray to *Renown*, G. R. Dodds to *Hood*, G. S. Irvine to *Revenge*, R. P. Phillips to *Echo*, C. P. Nicholas to *Shropshire*, and R. V. Jones to *Devonshire*.

ARMY MEDICAL SERVICES

Col. G. A. D. Harvey, C.M.G., has been selected for promotion to the rank of major-general with effect from Oct. 6th, and to be a Deputy Director of Medical Services in India, in succession to Major-General J. F. Martin, C.B., C.M.G., C.B.E.

Brevet Col. W. B. Purdon, D.S.O., O.B.E., M.C., Assistant Director of Hygiene, British Troops in Egypt, has been selected for appointment as Professor of Hygiene, Royal Army Medical College, with effect from August 18th, in succession to Colonel G. S. Wallace.

Brevet Col. J. M. Weddell, F.R.C.S., has been selected for appointment as Professor of Military Surgery and Consulting Surgeon to the Army, Royal Army Medical College, with effect from August 27th, in succession to Major-General J. W. West.

Col. H. M. J. Perry, O.B.E., Director and Professor of Pathology, Royal Army Medical College, will be promoted to the rank of major-general (supernumerary), with effect from Sept. 26th, and will continue in his present appointment.

ROYAL ARMY MEDICAL CORPS

Maj.-Gen. D. J. Collins, C.B., C.M.G., M.D., ret. pay (late R.A.M.C.) is apptd. Col. Comdt. (June 25), vice Maj.-Gen. Sir A. P. Blenkinsop, K.C.B., C.M.G., ret. pay (late R.A.M.C.), who has attained the age limit for his appt.

Short Serv. Commissions: Lt. (on prob.) R. Phillipson is restd. to the estabt.

REGULAR ARMY RESERVE OF OFFICERS

Lt.-Col. J. M. B. Rahilly, O.B.E., having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY RESERVE OF OFFICERS

Maj. I. J. Williams having attained the age limit retires and retains his rank, with permission to wear the prescribed uniform.

ROYAL AIR FORCE

Wing Comdr. D. McLaren to R.A.F. Depôt, Middle East, Aboukir, for duty as senior medical officer.

Squadron Leaders C. A. Lindup to Aeroplane and Armament Experimental Establishment, Martlesham Heath, for duty as medical officer; A. A. Townsend to

(*Continued at foot of next page*)

PUBLIC HEALTH

Mental Deficiency Certification

NEW Mental Deficiency Regulations, issued by the Minister of Health, contain changes of interest for the medical practitioner. In the procedure on petitions, for instance, the period of time between the examination of the patient and the presentation of the petition has been extended from 7 to 21 days. A new form of medical certificate (P4), for all cases dealt with by petition, obliges the doctor to state that he has read the statutory definitions—of "idiots," "imbeciles," "feeble-minded persons," and "moral defectives"—in Section 1 of the Mental Deficiency Act of 1927. A circular letter, sent out by the Board of Control with the new regulations, draws the particular attention of certifying medical practitioners to the new Article 18. This enjoins that every medical certificate accompanying a petition must state the facts on which the signatory has formed his opinion that the alleged defective is a defective within Section 1 of the 1927 Act; it must distinguish facts observed by the signatory himself from facts communicated by others, and an order is not to be made upon a certificate not founded wholly or in part upon facts observed by the signatory. No order is to be made unless each signing doctor has personally examined the patient within 21 days of the presentation of the petition. The Board of Control remarks that it is desirable that the medical certificates should be obtained from medical practitioners who have some knowledge of the patient's history or who possess special experience in dealing with mental deficiency. Section 5 (2) of the 1913 Act requires, of course, that one medical certificate shall be signed by a medical practitioner approved for the purpose by the local authority or by the Board. The old regulations of 1914 endeavoured to secure that one certificate be given by the patient's usual medical attendant. The Board now says that this latter requirement has proved impracticable. The new regulations make so such stipulation, but the Board expresses a hope that, where it is known that the alleged mental defective has been under the regular care of a medical practitioner, every effort will be made to obtain from him one of the certificates to accompany the petition. Article 18 prohibits signature of a certificate by the petitioner or by the petitioner's husband or wife, father or son, mother or daughter, brother or sister, or by certain other relations, or by a partner or assistant. An order sending a defective to an institution or certified house, or placing him under guardianship, is not to be made where a certificate or statutory declaration accompanying the petition is signed by the managers of the institution, or the owner of the certified house, or by the proposed guardian, or by anybody interested in payments for the patient's maintenance, or by the superintendent, or medical officer of the institution or certified house, or by the husband, wife, father, mother or other specified relatives, or the partner or assistant of any of the foregoing persons. It is hard to see what further precautions could have been enacted to exclude any possibly improper interest in the proceedings.

The new regulations are slightly shorter in places than the original provisions of 1914 and 1915. Certain administrative matters are left to be dealt with by circular. The Board expects that local authorities will coöperate closely with local education authorities, police authorities, public assistance committees, institutions and charitable societies or voluntary associations. It rightly emphasises, too, the need for early medical examination of any case of mental defect brought to the notice of the local authority, and for full information of the patient's history and circumstances. If a patient is moved into another local authority's area, this information is to be forwarded to that area. With the rest of the regulations dealing with the management of institutions and certified houses, with guardianship and the steps required when a patient is transferred from guardianship to an institution, and with the system of licensing and leave of absence there is here no space to deal. It may be mentioned, however, that the Board is reminding local authorities of the need of suitable medical attendance for defectives who are under guardianship. Guardians are to be told of the medical arrangements made, and of the steps to be taken immediately medical aid becomes necessary. The Board considers that guardians should not have recourse to a relieving officer to secure medical attendance for patients; provision for this, the Board observes, should be made under the Mental Deficiency Acts. If the new system seems complicated by its reliance on the threefold elaboration of statutes, regulations, and administrative circulars, it gives evidence at any rate of a progressive and sympathetic policy.

(*Continued from previous page*)

R.A.F. Station, Worthy Down, for duty as medical officer; E. D. D. Dickson to Central Medical Establishment, for duty as Medical Officer with No. 2 Central Medical Board; R. W. White to No. 1 Air Defence Group Headquarters, for duty as medical officer.

Flight Lts. R. N. Kinnison to R.A.F. Officers' Hospital, Uxbridge; M. T. O'Reilly to No. 25 (F) Squadron, Hawkinge; G. O. Williams to Central Medical Establishment; C. R. Palfreyman to Central Medical Establishment.

Flying Offr. J. S. Wilson to No. 26 (Army Coöperation) Squadron, Catterick.

Colonel N. Low, D.S.O., O.B.E., of Lucknow District Staff, is appointed Deputy Director of Medical Services, Eastern Command (Headquarters—Naini Tal), while Major-General C. W. F. Melville is on leave.

Major-General J. F. Martin, C.B., C.M.G., C.B.E., Deputy Director of Medical Services, Western Command (Headquarters—Quetta), is granted two months' leave from August 8th.

Cerebro-spinal Fever in Three Countries

The May issue of the *Bulletin* of the Office International d'Hygiène Publique contains reports on cerebro-spinal fever in India, the Anglo-Egyptian Sudan and Belgrade. Lieut.-Colonel A. J. Russell says that there have been several outbreaks in India since 1932, the most important being those of 1932–33 in the Borstal Institute at Lahore in the Punjab, where there were 27 cases with 11 deaths; of 1933–34 at Ahmadabad in the Bombay Presidency, where there were 592 cases with 271 deaths, and of 1933–34 in the city of Delhi where there were 127 cases with 122 deaths. Also sporadic cases have been notified in Chittagong and Baranagar in Bengal and in the city of Lahore, the Bombay Presidency, the Central Provinces, the North-west Frontier Province, Rajputana, the Central States, and Burma. During the first six months of 1934 1991 cases with 1216 deaths were notified in the whole of India, but these figures do not represent the complete incidence and mortality of the disease owing to the insufficient returns made. In India as elsewhere the deaths were most numerous in childhood and adolescence. As regards the types of meningococci most of those from the Delhi cases belonged to Type III., while of 35 strains from Calcutta cases 18 belonged to Type I. and 17 to Type III. Prophylactic vaccines prepared at the Kasauli Central Research Institute were being used, but it was too soon to come to any conclusion as to their value. No antimeningococcus serum had been prepared in India, and the results obtained with English serum had not been entirely satisfactory.

In his account of the severe outbreak of cerebro-spinal fever which occurred in the province of Kordofan in the Anglo-Egyptian Sudan in January to May, 1934, Mr. O. F. H. Atkey, F.R.C.S., states that there was a total of 4108 cases with 3251 deaths. Most of the patients belonged to the poorer classes; 78 per cent. were under twenty years of age; 43 per cent. were females, and of these 62·5 per cent. were under ten years. The only really successful preventive measure was evacuation of the affected villages, and in some instances complete reconstruction of the houses and installation of proper ventilation were carried out.

According to Prof. T. Simitch outbreaks of cerebro-spinal fever have hitherto been rare in Yugoslavia. During the last ten years the disease has only made a sporadic appearance in Belgrade. From 1926 to July, 1934, only 92 cases, of which 68 were in males and 24 in females, were treated at the Belgrade Clinic for infectious diseases. There were 45 deaths, of which 35 were in males and 10 in females. Treatment consisted in injection of antimeningococcus serum from various sources for 7–8 days in succession, two injections daily being given in the severest cases, in which the total dosage ranged from 120 to 200 c.cm. In cases in which a sufficient quantity of cerebro-spinal fluid was not withdrawn subcutaneous as well as intrathecal injection of meningococcus endotoxin was given, but the results were inconclusive.

Consultants in Municipal Hospitals

Dr. R. Veitch Clark, medical officer of health for Manchester, has prepared a scheme for the reorganisation of consultant services at three general hospitals in the charge of the public health committee—namely, Withington, Crumpsall, and Booth Hall. This scheme, which is now to be submitted to the city council, is intended to overcome three main defects in the present system: first, that the patient sees a consultant only if his condition seems to make consultation necessary; secondly, that the number of consultants and the number of visits they pay is quite inadequate; and thirdly, that the terms on which consultants are employed are unsatisfactory. In voluntary hospitals the visiting physicians and surgeons are actually (not nominally) responsible for diagnosis and treatment, and accordingly every patient is seen by a consultant as soon as possible after admission. In Dr. Veitch Clark's opinion this practice should be established in the municipal hospitals. He pays a warm tribute to the existing consultant staff; they have given their services unstintingly, putting in many more routine attendances than is required by their agreements and paying special visits daily or even more frequently according to the needs of the patients. Experience has shown, however, that the more effective the consultant practice in a hospital, the higher is the level of attainment reached by the hospital as a whole, and efficiency demands that the consultant staff shall be personally in charge of *all* acutely ill cases in the hospital. In preparing the scheme the object has been to allow for its development along lines which will make possible the closest collaboration with the work of the voluntary hospitals. The medical officer of health feels that if a single purpose is to animate the provision of the hospital needs of Manchester, both by the city council and by the voluntary hospital organisation, one of the best means towards this end is to interlace the actively practising medical staffs in such a way as to lead not only to fusion of interests but to collaboration, if not fusion, of practice.

The cost of the scheme as at present drafted will be £8000 a year. The *Manchester Guardian* of June 19th, from which these details are reproduced, describes it as one of the most important steps ever taken for the improvement of the public health services of the city.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 15TH, 1935

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 0; scarlet fever, 1688; diphtheria, 857; enteric fever, 17; acute pneumonia (primary or influenzal), 759; puerperal fever, 55; puerperal pyrexia, 124; cerebro-spinal fever, 23; poliomyelitis, 23; encephalitis lethargica, 5; *continued fever,* 1; dysentery, 10; ophthalmia neonatorum, 85. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 21st was 2844, which included: Scarlet fever, 884; diphtheria, 1062; measles, 43; *whooping-cough, 393; puerperal fever, 28 mothers* (plus 8 babies); encephalitis lethargica, 269; poliomyelitis, 1. At St. Margaret's Hospital there were 18 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 28 (0) from measles, 3 (0) from scarlet fever, 19 (6) from whooping-cough, 31 (0) from diphtheria. 38 (8) from diarrhœa and enteritis under two years, and 41 (4) from influenza. The figures in parentheses are those for London itself.

Sunderland reported the only fatal case of enteric fever. Six deaths from measles occurred at Sunderland and Birmingham, 5 at Liverpool. Bradford and Liverpool each reported 3 fatal cases of diphtheria; Newcastle-on-Tyne, Wakefield, Birmingham, and Plymouth each 2. Six deaths from diarrhœa occurred at Liverpool, 3 at Newcastle-on-Tyne.

The number of stillbirths notified during the week was 286 (corresponding to a rate of 47 per 1000 total births), including 48 in London.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A second refresher course in medicine, surgery, and the specialties, intended primarily for general practitioners, will be held at the Prince of Wales Hospital, London, N., from July 1st to 13th. A course in proctology is being given at St. Mark's Hospital from July 1st to 6th, and one in urology at the All Saints' Hospital from the 8th to the 27th. There is also to be a week-end course in general medicine and surgery at the Southend Hospital on July 13th and 14th, and a course in dermatology at the Blackfriars Hospital on week-day afternoons from the 15th to the 27th. Other items will be found in our Medical Diary. A panel of teachers is prepared to give clinical instruction in various branches. Full particulars may be had from the Fellowship at 1, Wimpole-street, London, W. 1.

CORRESPONDENCE

PROGNOSIS OF DIVERTICULITIS

To the Editor of THE LANCET

SIR,—I am a little surprised at the gloomy view aken by Mr. E. G. Slesinger regarding the prognosis f colo-vesical fistula complicating diverticulitis. r. Slesinger writes: "The prognosis in such cases always grave, and unless the cystitis is speedily elieved renal infection and death frequently follow." ome little time ago, largely through the courtesy f Sir John Thomson-Walker, I was able to investigate teen cases of this rare condition.[1] One of the st striking features of colo-vesical fistula is the lerance which the bladder develops to the presence f the fæcal material passing into it from the sigmoid olon. In only one of my cases was there evidence of infection ascending towards the kidney, the symptoms being limited to one attack of acute pyelitis, from which the patient recovered.

Regarding the treatment, Mr. Slesinger advises a colostomy with spur formation as the first essential, to be followed later by the radical operation upon the fistula, but I very much doubt the wisdom of thus setting forth a routine method of procedure. It is clear that in a number of cases the patient will be not fit to stand the radical operation, which necessarily carries a high mortality and unfortunately gives no guarantee of a permanent cure. Thus many patients will be left with a permanent colostomy. Reference to my cases shows how undesirable this may be, for again there is no guarantee that colostomy will improve the bladder condition to any appreciable extent. In one case the fistula actually developed twelve months *after* colostomy had been performed to relieve the diverticulitis. In a number of my cases the symptoms of diverticulitis itself improved considerably once the fistula into the bladder had formed, for this instituted a natural means of drainage of the inflammatory mass in the colon. The bladder symptoms are not severe, except possibly for the first few months after perforation has occurred, and the average patient will probably prefer to put up with the discomfort of these symptoms rather than the discomfort of a colostomy, especially as the surgeon cannot state definitely that colostomy will cure the bladder symptoms. In twelve of the nineteen cases no operative treatment was performed. One of these had been lost sight of, but in the other eleven the patient remained in fair health, only one of them developing ascending infection. Cystoscopy carried out on these patients showed the bladder wall to be remarkably free from cystitis except for a small area surrounding the opening of the fistula. Of four patients in whom the radical operation was performed, the fistula recurred in one and the patient therefore did not benefit. In the second, the first attempt at closure failed but the second attempt was successful. In the other two cases stormy convalescence followed operation but the patients finally recovered. It is clear therefore that although in theory the radical treatment is the ideal procedure it is only applicable to a few cases in whom the fistula is not of long duration and who can be regarded as good operative risks. I am in complete agreement with Mr. Slesinger that a preliminary colostomy should be done a considerable time before the direct attack upon the fistula is made.

Regarding the incidence of diverticulosis, Mr. Slesinger's figure of 10 per cent. of people over the age of forty is probably an overstatement. W. J. Mayo found diverticula post mortem in 5 per cent. of people over the age of forty and nearly 40,000 X ray examinations showed the percentage to be 5·7 per cent. Rankin and Brown estimated this at a similar figure. In my own series the incidence is 10·8 per cent. in 507 examinations of patients over the age of 35, but as I have pointed out elsewhere[2] this gives no true picture of the incidence among the public at large but is confined to that small group of patients in whom X ray examination is undertaken because they are complaining of symptoms referred to the large bowel.

I am, Sir, yours faithfully,

HAROLD C. EDWARDS.

Queen Anne-street, W., June 24th.

AGGLUTINATION OF VIRUS BODIES

To the Editor of THE LANCET

SIR,—In the interesting and important contribution by B. Schlesinger, A. G. Signy, and C. R. Amies to THE LANCET of May 18th concerning the presence of elementary bodies in acute rheumatism there is a sentence that in the interests of historical accuracy requires qualification. Before dealing with agglutination of these elementary bodies by the serum of the rheumatic patients, the writers proceed: "It has been already shown in a number of virus diseases that elementary bodies which on other grounds are regarded as the causal agents are specifically agglutinated by the corresponding antisera. This phenomenon was first described by Ledingham (1931) in the case of vaccinia and fowl-pox," &c. Now, Sir, agglutination of the elementary bodies of vaccinia by specific serum was known for a considerable time before 1931. Prof. Paschen has informed me that he demonstrated it to a local biological society at Hamburg so far back as 1911, and he has sent me an illustration showing his elementary bodies agglutinated in this way that is on a proof stamped with the date Dec. 31st, 1913. The article in question was prepared for a second edition of Kraus and Levaditi's valuable book on methods and technique in immunity investigations, and it is a great pity that owing to the war this article was never published. In 1920 however vol. ii. of the well-known text-book the "Handbuch der Pathogenen Protozooen" edited by v. Prowazek and Nöller was published, and on p. 936 there is a specific reference to this matter in an article by Rocha Lima and the statement is made that positive agglutination of the vaccinia elementary bodies had been obtained both by Belin, and by Paschen and Jacobstal. Yet another reference to the subject occurs in the most recent German work on small-pox and vaccination the "Handbuch der Pockenbekämpfung und Impfung" edited by Lenz and Gins, and published in 1927. On p. 848 in course of an article on the immunity relations between human and animal pock disease Sobernheim mentions that both macroscopic and microscopic agglutination of the elementary bodies of vaccinia by specific serum had been observed by Paschen.

There can be little doubt therefore, that in this matter of the specific agglutination of the elementary bodies of vaccinia a priority of many years belongs to Paschen. The statement made by Schlesinger, Signy, and Amies however would probably be quite correct if the qualification were added "in this country." The technique developed by Ledingham, notably his application of the high-speed centrifuge for the purpose of concentrating the filtered elementary bodies, and the patient observation of their agglutination under the microscope with adequate controls, has provided the groundwork of a method that is an important advance, and has already led to results of the greatest significance and promise as the published work shows including this latest contribution to the ætiology of acute rheumatism.

---

[1] Brit. Med. Jour., 1934, ii., 120.

[2] THE LANCET, 1934, i., 169 and 221.

The *macroscopic* method, however, of observing the flocculation of a virus by specific serum has many advantages over the microscopic, and has the merit of having already proved its practical usefulness in the field for detecting cases of small-pox by the presence in them of variola virus during an epidemic of small-pox at Dundee in 1927. Since this seems to have been the first occasion on which cases of a virus infection were identified by specific flocculation of the particular virus infecting them, it is possible that the special reports (Nos. 143 and 156) to the Medical Research Council on this matter by Burgess, Tulloch, and Craigie may come to be regarded in the future as of historic importance. Craigie's analysis of the specific flocculation reaction for small-pox demonstrated that two factors are involved in it—namely, agglutination of the elementary bodies, and precipitation of their soluble products. During the past few years moreover in a series of able researches carried out in the Connaught Laboratories of Toronto University, Craigie has shown not only that the separated and washed elementary bodies of vaccinia excite the production of specific agglutinin and complement-fixing antibodies, but also that this elementary body antigen is complex and comprises two fractions, one of which is more resistant to heat than the other. He has shown further that from these same separated and washed elementary bodies a specific precipitable substance can be extracted.

All of this goes to indicate that in course of time the various viruses will be recognised not only by the specific agglutination of their morphological elements, but also by specific precipitation of their soluble contents. It may be added that some experiments on this matter with Seitz filtrates of the viruses of vaccinia and of Shope's fibroma during recent months have convinced me that a specific precipitin test is quite practicable for the purpose of identifying the presence of either of these viruses, and has many advantages.—I am, Sir, yours faithfully,

M. H. GORDON.

St. Bartholomew's Hospital, June 21st.

DEAF EDUCATION AND LEGISLATION

To the Editor of THE LANCET

SIR,—I feel that the reply of Sir Hilton Young to Dr. Addison's question in the House of Commons, as reported in your issue of June 15th, asks for serious criticism. Dr. Addison asked the Minister of Health whether he was prepared to introduce legislation giving to deaf and dumb persons similar benefits as well as facilities for training as were afforded to the blind under the Blind Persons Act. Sir Hilton Young replied "No, Sir, I am not satisfied that there is need for such legislation."

It is time that the public should know the truth. My work for the deaf during the past quarter of a century has shown me that the outlook for deaf education in this country is worse now than it has been for many years and that fresh legislation is an urgent need; an opinion with which, I venture to think, no disinterested worker for the welfare of the deaf can disagree. My old friend Dr. James Kerr in 1933 put the matter forcibly in an article in the *Medical Officer* (1933, i., 261), from which I make two important quotations. "The various results of Blind Persons Act, 1920," he says, "shows what could be done on behalf of the deaf, if their care was recognised as a social duty of the community. For the deaf, however, there is no special provision beyond rather insufficient educational arrangements for deaf children." Dr. Kerr makes the following important demand for fresh legislation: "A Deaf Persons Act is much overdue, both from the educational and social points of view . . . . Such a Bill ought to be non-contentious and agreed, as its general principles have been recognised in recent legislation."

Unfortunately, the Eichholz report, with its inability to reconcile its own figures, its contradictions and vagueness, has put back the cause of the deaf for at least a generation, since it forms a potent weapon in the hands of reactionaries who maintain that the present inadequate and obsolete system is all that can be desired. *Quis custodiet ipsos custodes?*

I am, Sir, yours faithfully,

MACLEOD YEARSLEY.

Harley-street, W., June 24th.

CLEFT PALATE

To the Editor of THE LANCET

SIR,—Mr. Wardill's interesting paper in your last issue emphasises the importance of a good anatomical result in operations for cleft palate. There is, however, another side of the problem, well summarised in the statement that "in its last analysis the modifications and interruptions of the vocal sounds essential to enunciation are just as dependent upon muscular action as is the act of walking."[1] Children born with cleft palates are born with abnormal palatal muscles, and it is not unreasonable to assume that many of them also have abnormal innervation to these muscles, which delays or even prevents their efficient cerebral control. In any operative attack upon the palate the aim must be to place the musculature in the optimum position for functional activity, and operation should be followed by a course of training to enable the child to establish coördination. The palatopharyngeus and the superior constrictor muscle play a very important part in the mechanism of enunciation and speech, and if a child has efficient control of these muscles he may speak well in spite of a palate which appears to be shortened.

Pharyngoplasty, which was attempted even in pre-Listerian days, has been alternately used and discarded by surgeons the world over. It was brought into prominence by Rutenberg in 1876; he made a transverse incision in the pharynx and sutured it longitudinally. Botey in 1908 excised an ellipse from the posterior pharyngeal wall, and sutured the edges, while Sir Robert Woods in 1927 electrocoagulated the posterior pharyngeal wall. Mr. Wardill has modified and reintroduced Rutenberg's operation—evidently with some success—but I cannot help thinking that narrowing of the lumen of the nasopharynx is liable to interfere with the function of the palatopharyngeal sphincter.

Like Mr. Wardill, I am strongly in favour of early operation so that the repair can be carried out before faulty habits of diction have been formed. Most children, however, speak before they are two years old, and personally I agree with Veau and others that the operation should be done if possible at the tenth month of life.

---

[1] Blair, V. P., and Brown, J. B.: Surg., Gyn., and Obst., 1934, lix., 309.

Should the palatopharyngeus be underdeveloped, the palate abnormally short, and the nasopharynx appear wide, the ultimate functional result will probably be poor. Many attempts have been made to overcome these deficiencies, and G. M. Dorrance has suggested a push-back type of operation for the purpose. Unfortunately, however, he leaves a large raw area on the nasal side of his flap which is thus liable to undergo cicatrisation and subsequent contracture. At the present time the greatest chances of success lie first with the freeing of the palatal attachments to the posterior edges of the palate bones, and particularly to the division of the hamular process round which the tendon of the tensor palati turns. This was advocated by Whitehead in 1868, but he made the mistake of dividing the muscle as well. Secondly, all raw surfaces should be epithelialised. Thirdly, a course of speech training should be instituted after the operation. This training may be left to be carried out by the mother, but her task will be made easier if she works in collaboration with a person skilled in the after-care of this type of case. I am, Sir, yours faithfully,

DAVID LEVI.

Harley-street, W., June 24th,

TREASURE TROVE

To the Editor of THE LANCET

SIR,—May I make a slight correction in your note on this subject in THE LANCET of June 8th (p. 1351)? The notice circulated to Chief Constables in 1925 has been superseded by one of 1931. By the new regulations no deduction is made from the payment of the full market value to the finder who honestly reports his find. I enclose a copy. The jury who found that the single guinea of 1745 picked up at Newbury was not treasure-trove were quite right. For a find to be treasure-trove there must be evidence or presumption that it was deliberately hidden; otherwise it is ordinary trove, and the finder has the right to it against all the world except the owner, if he can be traced.

I am, Sir, yours faithfully,

British Museum, W.C., June 19th. GEORGE HILL.

*** We are grateful for Sir George Hill's correction on a matter which deserves more publicity than a notice from the Home Office to chief constables can give. Possessors of the latest edition of Jervis on Coroners may note that the information which follows supersedes the statement on p. 270 of that admirable work.—ED. L.

REVISED REGULATIONS FOR TREASURE-TROVE

Objects of *gold or silver* (whether coin, plate or bullion) which have been *hidden* in the soil or in buildings, and of which the original *owner cannot be traced*, are Treasure-Trove, and by law the property of the Crown.* If, however, the finder of such objects reports the find promptly, and it is decided that it is Treasure-Trove and therefore the property of the Crown, he will receive its *full market value* if it is retained for the Crown or a museum. If it is not retained, he will receive back the objects themselves with full liberty to do what he likes with them; or, if he wishes it, the British Museum will sell them for him at the best price obtainable. The only way in which a finder can comply with the law and also obtain these advantages is by reporting the find promptly to the proper authority.

The proper authority is the Coroner for the District in which the find is made, for he is the authority who enquires "of treasure that is found" and "who were the finders." (Coroners Act, 1887, section 36.)

Anyone therefore who finds such objects should report the find to the Coroner, either direct, or through the local Police, or by writing to the Director, British Museum, London, W.C.1, who will communicate with the Coroner.

Coins and other ancient objects of copper, bronze or any metal other than gold or silver are *not* Treasure-Trove and finds need not be reported to Coroners. But the British Museum is glad to hear of such finds and, if they are reported to the Director, will in suitable cases arrange for purchase or sale.

Any further information may be obtained by applying to the Director, British Museum, London, W.C.1.

THE EFFECTS OF HOT CLIMATE

DR. D. H. K. LEE writes: May I draw your attention to an error which appeared in the rough proof of my address to the Royal Society of Tropical Medicine and Hygiene, and which has been repeated in an annotation in your issue of May 25th The critical level for serum chloride concentration in the production of "heat cramps" is 100 *mille-equivalents* per litre, and not 100 mg. as quoted. The former figure corresponds to 365 mg. per 100 c.cm. (a figure more familiar to British readers).

---

* Unless (as in some rare cases) the "Franchise of Treasure-Trove" has been expressly granted to a subject, in so far as finds in the particular locality are concerned.

OBITUARY

JOHN JOSIAH DOUGLAS, M.D., F.R.C.P. Edin., D.P.H. Oxon.

Dr. John Josiah Douglas, who died at Upper Norwood on June 13th after a brief illness, had practised in the district for 40 years. Born in 1866, he received his medical training at the University of Edinburgh where he graduated as M.B., C.M. in 1889. He took the diploma of M.R.C.P. Edin. and proceeded to the M.D. degree in 1897, being elected five years afterwards F.R.C.P. He was house physician at the Royal Infirmary, Edinburgh, and at the Norfolk and Norwich Hospital, and worked also in the Cancer Research Laboratory of the Middlesex Hospital, especially in connexion with the study of blood in malignant disease. He entered practice at Upper Norwood in 1895 and during his long residence there was particularly interested in the work of the Norwood Cottage Hospital. He had been surgeon to the hospital and at the time of his death was the senior member of the honorary medical staff. The organisation and progress of this institution owed him a real debt and his death was caused by an accident connected with his duties there. He had wounded his wrist at an autopsy at the hospital, and when the rapidly fatal course of his illness led to an inquest, the verdict returned, on the medical evidence, was to the effect that he had died from an infection incurred while carrying out the autopsy.

CHARLES H. S. TAYLOR, M.D. Camb.

WE regret to announce the death, which occurred on Tuesday last, of Charles Henry Shinglewood Taylor, well-known at Cambridge alike for his services in watching over the physical training of athletes and for his great ability and wide sympathy as a medical adviser and counsellor to the undergraduate world. Taylor was born in 1882 in Leribe, Basutoland, the son of Dr. Shinglewood Taylor, and was educated at St. Andrew's College, Grahamstown, and Rugby, whence he proceeded to Gonville and Caius College, Cambridge. He did his clinical courses at St. Bartholomew's hospital and graduated

M.B., B.Chir. in 1910, having already secured honours in the Natural Sciences Tripos. While at Cambridge he made a great reputation as an oar. As stroke of the Caius boat and later as stroke of the university boat he was marked alike for his beautiful style and his unfailing courage. His first medical appointments were at St. George's hospital where he served both as house physician and house surgeon, while he also did special work in the orthopædic departments at St. Bartholomew's hospital and Great Ormond-street children's hospital. On the outbreak of war he obtained a commission in the Royal Naval Division and saw service in Italy and Gallipoli; later he received a commission in the Royal Air Force upon its institution, and here his professional skill and his remarkable ability for making friends and for winning the confidence of his juniors led to his early promotion to the rank of lieutenant-colonel.

After the war Taylor returned to Cambridge and succeeded to the practice of Dr. R. W. Michell, also a member of Caius College, who had been killed in the war. Michell had for many years been medical adviser to many of the university clubs, notably to the boat club, and Taylor now assumed the responsibility of examining the physical condition of all sorts of candidates for athletic honours. Thus to some extent his early prowess on the river dictated his future professional career, but his unusually attractive personal qualities no less than his well-equipped brain would have secured success in any walk of life. He was the friend and confidant of a long series of undergraduates, and he devoted to their service a life that for many years was a frail one, and that in its latest period was a gallant combat against death.

JOHN HALL MORTON, M.D. Dub.

THE death occurred on June 7th of Dr. John Hall Morton, medical officer and governor of Holloway prison. He was born in 1883 in Limerick and received his medical education at the University of Dublin, where he graduated as M.B., B.Ch. in 1907. He spent his valuable life in the prison service after a short period as assistant medical officer in the Warwick County Lunatic Asylum. He was first assistant medical officer at the Richmond and Portrane Asylums, Dublin, and was then for a time deputy governor and medical officer at Borstal. He then became governor and medical officer at Aylesbury prison and 14 years ago was appointed governor and medical officer at Holloway, during the tenure of which post he died. His last active work was to make a report in writing, by permission, for the information of the court during the Stoner and Rattenbury case, his state of health not allowing him to give personal evidence. Dr. Morton was a recognised authority on alcoholism, holding strong views as to the futility of short sentences where the victims came into collision with the law; as a result he desired to see the institution of colonies for the victims of alcohol where they could, in a healthy environment, become self-supporting. He contributed on these subjects to the *Journal of Mental Science* and the *Howard Journal*, and earned well his reputation for efficiency, especially in regard to the treatment of women prisoners, and his humane attitude towards his charges.

HOSPITALS ON MERSEYSIDE.—In 1934 Merseyside hospitals received £140,285 from employers and workers as a result of the penny-in-the-pound contributory fund.

THE RESIGNATIONS AT THE ITALIAN HOSPITAL

FOR some time past there has been disagreement between the committee of management of the Italian Hospital and the medical committee with regard to the method of appointing new members of the honorary staff and other matters. This disagreement has now culminated in the resignation of 14 members of the staff. We understand that the first point of difference concerned the appointment as assistant physician of an Italian national who was duly registered by the General Medical Council under the reciprocity agreement between Great Britain and Italy, but had not, in the opinion of the medical committee, any special qualification for the post, having taken a higher examination only in surgical pathology. Soon after his appointment the new assistant physician found that he could not do surgery under the terms of that appointment, and the committee of management accepted his resignation and appointed him assistant surgeon instead. More recently there has been a further cause of friction. The committee of management, it is alleged, criticised the professional conduct of one of the honorary surgeons without having at any time given him an opportunity of appearing before them to explain his reasons for a course of action which, in the view of the medical committee, in any case called for no criticism. The atmosphere was therefore already strained when the appointment was made, without consulting the medical committee and without advertisement, of five new honorary medical officers, none of whom possessed the qualifications for an honorary post as laid down in the rules of the hospital. Of these officers, four were Italians, one of whom has the Conjoint diploma, the others being registered by reciprocity. Three of these five officers were given the title of "temporary honorary," and two of them were called "assistant honoraries," all with the same privileges as full members of the honorary staff. The committee of management at the same time gave notice of their intention to make such alteration of the rules of the hospital as to permit the appointment of as many "temporary honorary" officers as was thought desirable. They also proposed to allow supernumerary members of the hospital staff—e.g., casualty officer, out-patient officer—to sit on the medical committee with full voting powers.

At this stage the good offices of the B.M.A. were enlisted, with results that appeared at first to be satisfactory. Following a visit by Dr. G. C. Anderson, the medical secretary of the Association, the committee of management sent a letter of apology to the surgeon whose conduct they had criticised and consented (having previously ignored all representations) to appoint a subcommittee to meet representatives of the medical committee for a discussion of the points at issue. The two subcommittees met and the medical committee were promised a considered reply to their representations. This was not, however, forthcoming, and on June 18th the committee of management was asked by the medical committee to give definite assurances on five specific points, or to accept the resignations of almost the whole of the honorary staff. The committee of management refused to give these assurances and the hospital has thus lost the services of a group of distinguished men.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Overcrowding and Housing Standards

IN the House of Lords on Monday, June 24th, the Housing Bill was considered in Committee. The Earl of ONSLOW was in the chair.

On Clause 3 (which concerns offences in relation to overcrowding),

Lord BALFOUR of BURLEIGH moved an amendment to ensure that in fixing the standard of overcrowding regard should be had to the provisions of Section 37 of the Act of 1930. He said that the standard set up in the Bill was a penal standard and a very low one. The amendment only gave effect to a declaration which the Minister in charge of the Bill in the House of Commons had made.

Viscount GAGE, Lord in Waiting, said that what the Minister had intended to convey was that where housing had to be provided by the local authority Section 37 of the Act of 1930 should apply. Although the standard in the Bill was not an ideal one it was not undesirable compared with what the Government were trying to remedy.

The Bishop of WINCHESTER said that the late Minister of Health made it perfectly clear that new houses which were to be built under the Overcrowding Bill would conform to a higher standard than the standard laid down. There was nothing in the Bill which made that clear.

The amendment was negatived by 40 votes to 17.

The Housing Bill was further considered in Committee in the House of Lords on Tuesday, June 25th.

On Clause 30 (which deals with Exchequer contributions towards the provision of flats on sites of high value),

The Earl of DUDLEY moved an amendment to provide that the Minister of Health should not approve flats unless each flat in a block exceeding three storeys in height was provided with a balcony. He said that medical officers of health were unanimous in the opinion that balconies were essential for the health of infant children. A mother who lived at the top of a big block of flats had not time to take her children out into the air and sunshine. He was told that the lack of fresh air and sunshine was a greater cause of rickets and other diseases in children than malnutrition.

Viscount HALIFAX, Secretary of State for War, said that everyone would be in agreement with the object of the amendment, but he asked Lord Dudley not to press it. To single out and give prominence to one desirable amenity and to include it along with the provision of bathrooms in the Bill would by implication tend to diminish the importance that might be attached to other amenities equally desirable.

Lord BALFOUR of BURLEIGH suggested that in future circulars the proposal for balconies should be commended by the Minister to local authorities as a very desirable feature.

Viscount HALIFAX promised to convey that suggestion to the Minister.

The amendment was withdrawn and the Bill passed through Committee.

In the House of Lords on Monday, June 24th, the University of Durham Bill passed through Committee without amendment and was reported to the House.

The Superannuation Bill (which amends the law with respect to the superannuation of civil servants) passed through Committee and was reported to the House. The Bill passed through the Report stage on June 25th and was read the third time.

Medical Services Among African Natives

In the House of Commons on Thursday, June 20th, a vote of £35,133 was considered in Committee of Supply for the salaries and expenses of the Dominions Office.

Mr. J. H. THOMAS, in introducing the vote, announced that the Government had under consideration at this moment a grant of £100,000 from the Colonial Development Fund which he hoped to use mainly for the development of medical services in the African Colonies and Protectorates. In addition a grant of £10,000 had been made by the mineowners of South Africa which would be used exclusively for medical purposes among the natives.

The debate on the vote was adjourned.

HOUSE OF COMMONS

WEDNESDAY, JUNE 19TH

New Motor Driving Test

Mr. PARKINSON asked the Minister of Transport the number of men and women that had been examined for the new driving test, and the number that had failed, giving separate figures for men and women.—Mr. HORE-BELISHA replied: Up to and including June 15th 50,712 persons have been examined, of whom 5036 failed to satisfy the examiners. From May 6th, since when separate records for men and women have been kept, to June 15th the figures are:—

Men examined 19,459, failed 1989
Women ,, 4542 ,, 730

THURSDAY, JUNE 20TH

Potato Lifter's Death in Jersey

Mr. THORNE asked the Minister of Labour if he could give the House any information in connexion with the death of a potato digger at St. Helier, who was sent from Torrington labour exchange, Devon; if he could state the cause of death; and whether he received from time to time reports in connexion with the housing and working conditions of workers who were engaged from British labour exchanges to dig potatoes in Jersey.—Mr. ERNEST BROWN replied: Mr. Mules applied and was engaged for work as a potato lifter in Jersey. On June 6th he had a sudden collapse while at work and was conveyed to hospital, where, I regret to say, he died. Death was due to syncope arising from duodenal trouble. Mr. Mules had previously been employed on this work and there was no medical evidence to suggest that he was unfit for it. In a reply to the last part of the question it is the case that officers of the Ministry are stationed in Jersey throughout the potato lifting season, who keep in touch with conditions and furnish weekly reports.

Medical Examination of Coal Workers

Mr. E. WILLIAMS asked the Minister of Labour whether employment in the Kent coalfield was subject to medical examination, and the number who had recently been rejected for this reason; and whether unemployment benefit would be prejudiced.—Mr. ERNEST BROWN replied: The answer to the first part of the question is "Yes." I understand that 14 applicants for employment have been rejected on medical grounds this year. Eligibility for unemployment benefit is determined, as the hon. Member is aware, by the independent statutory authorities, but I am not aware of any cases in which a claim has been disallowed in these circumstances.

Young Offenders and Imprisonment

Mr. LOVAT-FRASER asked the Home Secretary whether, in view of the widespread condemnation of the practice of sending young people to prison, he would promote legislation to prevent young people between the ages of 17 and 21 from being subjected to imprisonment.—Sir JOHN SIMON replied: I most fully appreciate the objections to sentencing young offenders to imprisonment if any possible alternative is open to the Court. But the decision when to use one of these alternatives, such as probation or Borstal training, must be a matter for the discretion of the Court, having regard in each individual case to the facts of the offence and the character of the offender. Legislation removing all discretion from the Courts would not, I fear, be practicable.

National Health Insurance: Medical Treatment of Young Persons

Mr. CLARKE asked the Minister of Health whether it was his intention to include any organised provision for the medical treatment of boys and girls between the ages of 14 and 16 years in the Vocational Guidance of the National Health and Contributory Pensions Bill, 1935, in view of the position being anomalous now that the age of entry to unemployment insurance had been lowered.—Sir KINGSLEY WOOD replied: I would refer my hon. friend to the statement which the Parliamentary Secretary to the Ministry made on this subject in the course of his speech on the Second Reading of the Bill.

National Health Insurance: Doctor's Remuneration

Mr. HICKS asked the Minister of Health the annual amount paid to national health insurance doctors for the last three years; the amount paid out by the approved societies to their members during the same period; and *the amount paid to the drug fund during the same period* in Great Britain and Northern Ireland.—Sir KINGSLEY WOOD replied: The following particulars relate to England and Wales. As regards Northern Ireland I have not the desired information, and as regards Scotland I would refer the hon. Member to the Secretary of State for Scotland. The amounts paid to insurance practitioners (A) from National Health Insurance funds, including payments for drugs in certain circumstances, during the years 1932, 1933, and 1934, and of the amounts paid to chemists (B) in respect of National Health Insurance prescriptions were as follow:—

(A)		(B)	
Year.	Amount. £	Year.	Amount. £
1932	6,875,014	1932	1,994,393
1933	6,898,822	1933	1,948,090
1934	6,995,255	1934	1,945,056

The capitation fees payable to insurance practitioners and the dispensing fees payable to chemists were subject as from Oct. 1st, 1931, to June 30th, 1934, to an economy deduction of 10 per cent. and as from July 1st, 1934, to the end of the period covered by this statement to an economy deduction of 5 per cent.

The amounts paid in benefits (other than medical benefit) by approved societies during the same years were approximately as follow:—

Year.	Amount. £
1932	19,385,000
1933	19,240,000
1934	18,083,000

Housing Grants

Mr. DOBBIE asked the Minister of Health if any grants had been made under the Housing (Financial Provisions) Act, 1924, towards housing schemes not completed by June 30th, 1934; what they were; and what were the circumstances under which the grant had been made.—Sir KINGSLEY WOOD replied: In no case has a grant been made to a local authority in the circumstances described. In one case grant has been paid to a voluntary housing association, the Westminster Housing Trust, in respect of a large block of flats which could not be completed by June 30th, 1934. In this case there were exceptional reasons for the payment of grant for which special Treasury sanction was obtained. In particular, construction of the flats was begun on the strength of a promise of grant given in good faith by the London County Council before the abolition of subsidy was announced.

Burning Pit Heaps and Public Health

Mr. TINKER asked the Minister of Health if he was aware of the increasing number of burning pit-heaps in Lancashire and Yorkshire; and, in view of the danger to health that they caused, if he would have an investigation made by his department to find out the number the area covered by them.—Sir KINGSLEY WOOD rep I am aware that there are burning pit-heaps in Lanca and Yorkshire, but not that their number is incr An investigation was made last year and it was estim that there were 45 such heaps in Lancashire and Yorkshire.

Medical Officer's Duties in Scottish Priso

Mr. LEONARD asked the Secretary of State for Scot the terms of the prison rule, No. 225, governing the of the medical officer and the extent to which that was complied with in Barlinnie prison.—Sir GODF COLLINS replied: The rule to which the hon. Mem refers reads as follows: "The medical officer shall every prisoner at least once a week, so as to ascert general state of health, physical and mental, and wh he is clean in his person, and free from disease, and i clothing and bedding are sufficient, and shall record result of his inspection in his journal." The me officer sees every prisoner once a week and makes inq as to his condition. If the state or appearance of prisoner renders any action necessary, or if the pris makes any request or complaint which inquiry pr to be justified, action is duly taken. The medical o records the result of his inspections in his journal.

Provision of Pit-head Baths

Sir CHARLES EDWARDS asked the Secretary for M if he was aware that the workmen of the Ma colliery, Monmouthshire, had been agitating f head baths for the last five or six years; that a b was taken at that time and showed an overwh majority in favour; and that negotiatons were sup to have been going on between the colliery company the railway company, who owned the site, for the wh of that time, so far without result; and if he wo endeavour to bring these negotiations to an end so *the work might proceed.—Captain CROOKSHANK repli* I am aware of all the circumstances in this case, an greatly deplore the delay which has occurred in build the baths. There have been exceptional difficulties, in regard to the choice of site, part of which is the prop of the railway company, and as to the conditions of acquisition. The hon. Member is no doubt aware t the conduct of the negotiations is a matter for the colli company concerned, and not one in which I have a authority to interfere. My predecessor did all he could expedite a satisfactory settlement and I shall do the sa

Silence Zones

Mr. RANKIN asked the Minister of Transport whet any local authority had yet experimented with enforcement of silence zones for the whole 24 hours of day; and whether he was prepared to receive sym thetically applications to carry out such experiments. Mr. HORE-BELISHA replied: The answer to the first pa of the question is in the negative, and to the second pa in the affirmative.

MONDAY, JUNE 24TH

Hospital Treatment of Infectious Diseases in Sunderland

Mr. STOREY asked the Minister of Health whether had considered correspondence submitted to him by Sunderland Children's Hospital with reference to t refusal of the health committee of Sunderland Corporati to remove to the borough hospital for infectious diseas two children whose homes were outside the borough, a who were found to be suffering from cerebro-spinal men gitis after a short period of observation in the hospit until such time as the hospital authorities had ma arrangements with the local authority in the area which the children resided for the payment of the co of their maintenance and treatment; and what steps proposed to take to ensure that infectious cases were future removed promptly from th hospital the infectious diseases hospital. Parliamentary Secretary to the replied: My right hon. friend has received the corr ndence referred to and he will communicate with the nderland town council in the matter.

New Poisons Regulations

Captain **Peter Macdonald** asked the Home Secretary ether he had yet considered the report of the Poisons ard with regard to the new poisons regulations and s; whether he proposed to make any amendments hereto; and, if not, by what date it was proposed to the order for the enforcement of these proposals ore Parliament.—Captain **Wallace**, Under-Secretary the Home Office, replied: Notice of my right hon. nd's intention to confirm the Poisons List, prepared l submitted to him by the Poisons Board, and to make es under Section 23 of the Pharmacy and Poisons t, 1933, was published on the 18th of this month. I nnot say what amendments, if any, will be made in the ft list and rules until my right hon. friend has con- ered such representations as he may receive in regard them. The rules and the order confirming the Poisons st will, as required by the Act, be laid before Parliament soon as they are made.

Mental Hospitals

Sir **William Jenkins** asked the Minister of Health the mber of patients in mental hospitals in England and ales for 1926, 1930, 1933, and 1934; and the average st per head per week.—Sir **Kingsley Wood** replied: he available figures relating to county and borough ental hospitals are as follow:—

Jan. 1st—	Number of patients.	Average weekly cost per patient, excluding capital expenditure defrayed out of revenue (year ended March 31st).
1926	107,836	—*
1930	117,249	—*
1933	122,629	25*s.* 11·9*d.* (69 hospitals).
1934	123,977	25*s.* 7·1*d.*

* The figures for these years are not given as the form of sting Returns was revised as from April 1st, 1932; for the st year of its application (1932–33) only 69 of the 99 hospitals rnished such revised Returns.

TUESDAY, JUNE 25TH

Malaria in Ceylon

Mr. **Rankin** asked the Secretary of State for the olonies whether he was now in a position to make any tatement with regard to the steps which had been taken o control the exceptional outbreak of malaria in Ceylon; and whether he was satisfied that the steps now being taken were likely to put an end to this outbreak.—Mr. M. **MacDonald** replied: The steps which have been taken were detailed in oral replies given by my predecessor to questions on March 27th and June 5th. Since the latter date the Governor has reported that the State Council of Ceylon have recently voted a further sum of Rs. 2,000,000 for the relief of distress due to sickness and shortage of food arising from the malaria epidemic and the failure of the harvest. The new drug atebrin musonate is undergoing trials in the larger hospitals and certain groups of villages in the epidemic area. I am satisfied that the Government of Ceylon are taking all reasonable measures for dealing with the outbreak, and that they will give the fullest consideration to any further recommendations which may be made by the special officer who is engaged on an expert investigation of the situation.

Supply of Fresh Milk to Home Troops

Mr. **Patrick** asked the Financial Secretary to the War Office the approximate proportion of fresh and preserved milk, respectively, consumed by troops stationed in the United Kingdom; and whether, in the interest of the health of the troops and that of home milk producers, he would consider the possibility of taking steps to increase the proportion of fresh milk consumed.—Mr. **Douglas Hacking** replied: Milk is purchased for the troops regimentally from the Navy, Army, and Air Force institutes out of a daily cash allowance, and it is within the discretion of units whether they purchase fresh or preserved milk, both of which are obtainable from the institutes. Definite information is not available as to the proportions of fresh and preserved milk consumed, but I can assure my hon. friend that the importance of using fresh milk is impressed both on the messing officers of units and on the soldiers' families.

Miners' Phthisis in Basutoland

Mr. **Paling** asked the Secretary of State for Dominion Affairs how many Basutos were employed in the mines of the neighbouring territories, and how many had been certified, after a period of work in the mines, as suffering from miners' phthisis.—Lord **Stanley**, Under-Secretary of State for the Dominions, replied: According to the recent report of the Basutoland Commission the average number of Basutos employed in the Witwatersrand Gold Mines during 1931–33 was 29,374. I have no information as to the number of Basutos who are suffering from miners' phthisis contracted as a result of such employment, but the total number of cases of pulmonary tuberculosis reported in Basutoland during the period in question averaged 323 a year.

MEDICAL NEWS

University of Cambridge

At recent examinations the following candidates atisfied the examiners:—

THIRD EXAMINATION FOR M.B. AND B.CHIR.

Part I. (Surgery, Midwifery, and Gynæcology).—R. A. Andrews, M. Ball, S. L. Bhatia, G. B. Barbour, K. O. Black, A. C. Blandy, A. W. Bone, R. E. Bonham-Carter, A. S. Bookless, A. F. Bryson, I. B. Bunting, H. A. Burt, G. R. Debenham, C. A. Dowding, D. G. Evans, R. D. Ewing, I. C. Fletcher, R. T. Gabb, C. J. Gordon, C. N. Gosse, G. N. St. J. Hallett, A. E. M. Hartley, W. S. Haynes, H. D. Johnson, A. R. Kelsall, J. R. Kerr, J. W. acey, W. A. Law, S. A. H. Lesser, J. F. Lown, K. G. F. Mackenzie, H. S. Mellows, C. R. Morison, W. G. Murray-Browne, K. O. G. Norman, D. M. Norman-Jones, G. W. Palmer, A. H. Pirie, R. R. Prytherch, C. N. Pulvertaft, C. G. Rob, V. C. Robinson, P. G. Scott, C. W. A. Searle, J. A. Seymour-Jones, R. Solley, A. F. Stallard, R. H. Taylor, F. B. Thomas, G. C. Tooth, W. Warren, H. S. Wigfield, B. L. Williams, A. Winder, and C. H. F. Wood.

Part II. (Physic, Pathology, and Pharmacology).—A. W. Abramson, D. G. Allen, H. F. Anderson, T. G. Armstrong, E. Bevan, G. Blackburn, W. G. Brander, S. G. Brook, J. W. D. Ball, N. A. Buxton, A. G. Carr, A. E. Cohen, J. S. Cookson, J. F. Coombs, T. M. Daniel, R. B. Davis, G. R. Debenham, W. J. B. de Gruchy, J. F. Dow, E. P. H. Drake, T. S. R. Fisher, L. C. Fletcher, R. T. Gabb, L. R. Gardner, C. J. Gordon, E. M. Griffin, N. J. P. Hewlings, E. D. Hoare, R. D. Holloway, M. Hynes, R. F. Jarrett, A. R. Kelsall, D. P. King, W. A. Law, H. T. Laycock, N. C. Lendon, P. H. Lenton, L. N. G. Lytton, E. C. Manson-Bahr, F. R. R. Martin, T. D. F. Money, D. M. Norman-Jones, J. F. Paterson, J. H. Patterson, E. E. Pochin, G. R. Rawlings, J. S. Richardson, M. C. A. Robson, R. E. Rodgers, J. R. Rose, C. W. A. Searle, H. S. Sharp, A. H. M. Siddons, F. A. Simmonds, D. A. Smith, J. H. Stothert, O. K. Tubby, W. F. Walton, J. G. Webb, H. S. Wigfield, and H. M. Wilson.

University of Bristol

At recent examinations the following candidates satisfied the examiners:—

M.D.

J. F. Coates (with distinction).

M.B., CH.B.

Section II.—Kathleen G. Brimelow (with second-class honours), and S. D. Loxton (with distinction in surgery).

B.D.S.

J. W. E. Snawdon (with second-class honours).

University of Glasgow

On June 19th the hon. degree of LL.D was conferred on Dr. Walter King Hunter, emeritus professor of the Muirhead chair of medicine in the University, Dr. John Martin Munrow Kerr, emeritus professor, of the regius chair of midwifery in the University; and Dame Louise McIlroy, late professor of obstetrics and gynæcology in the University of London.

The following degrees were also conferred:—

M.D.—D. F. Anderson, Eleanor Badenoch, Thomas Nicol, and J. B. Rennie (with honours); William Gilmour, and Jessie W. Ogilvie (with high commendation).

M.Ch.—T. J. B. A. MacGowan (with high commendation).

Society of Apothecaries of London

At recent examinations the following candidates passed in the undermentioned subjects :—

Surgery.—N. F. Bishay, Univ. of Birmingham ; E. M. Craggs, Middlesex Hosp. ; C. R. Hopper, Univ. of Liverpool ; J. B. Mair, Univ. of Glasgow ; J. E. T. Munn, St. Mary's Hosp. ; S. Roberts, Univ. of Bristol ; and J. S. Scott and D. Walton, Univ. of Manchester.

Medicine.—A. Aspinall, Univ. of Manchester ; N. A. Bicchieri, St. George's Hosp. ; S. E. Osborne, Guy's Hosp. ; and S. Roberts, Univ. of Bristol.

Forensic Medicine.—A. Aspinall, Univ. of Manchester ; G. G. O. Evans, Charing Cross Hosp. ; S. E. Osborne, Guy's Hosp. ; S. Roberts, Univ. of Bristol ; G. W. Van Mentz, London Hosp. ; and H. M. R. Waddell, Univ. of Manchester and Charing Cross Hosp.

Midwifery.—E. E. Le Feuvre, St. Mary's Hosp. ; and J. B. Mair, Univ. of Glasgow.

The following candidates, having [illegible] tion, have been granted the diploma [illegible] to practise medicine, surgery, and [illegible] J. S. Scott, H. M. R. Waddell, and D. Walton.

University of St. Andrews

Dr. Robert C. Garry, of the Rowett Research Institute, Aberdeen, has been appointed to the chair of physiology at University College, Dundee.

Dr. Garry graduated in medicine at Glasgow in 1922, winning the Brunton memorial prize. After a year as resident at the Western Infirmary he took up work at the Institute of Physiology, later becoming assistant to the late Prof. Noel Paton. In 1925 he was appointed lecturer and Muirhead demonstrator in experimental physiology under Prof. E. P. Cathcart. In the period from 1926 to 1929 he studied at Freiburg, at University College, London, and at Leeds, after which he returned to Glasgow as lecturer and examiner in physiology. In 1933 he received the degree of D.Sc., and in February of last year joined the staff of the Rowett Research Institute. Dr. Garry's research work has been chiefly concerned with nutrition, especially in relation to gastro-intestinal function.

Prof. David Waterston, of the chair of anatomy, has been reappointed representative of the university on the General Medical Council for a period of five years.

Post-graduate Course in Freiburg

A special course is being held from July 1st to 23rd by the medical faculty of the University of Freiburg. The lecturers will include Prof. L. Aschoff, Prof. P. Uhlenhuth, Prof. C. Noeggerath, and Prof. K. Schilling. Further information may be had from the Prof. Noeggerath at the Kinderklinik, Mathildenstr, 1, Freiburg-in-Breisgau, Germany.

Wilson Hospital, Mitcham

On June 22nd Dr. Alfred Cox opened extensions at this hospital comprising a new theatre and out-patient block and new wards. A total of 72 beds are now available. Passages from Dr. Cox's address appear on p. 1521.

Treloar Cripples' Hospital and College

At the founders' day celebrations of the Lord Mayor Treloar Cripples' Hospital and College, to be held at Alton on Saturday next, July 6th, Lord Reading will lay the foundation stone of the Silver Jubilee treatment centre.

The Patient's Outlook

Addressing the students of St. Thomas's Hospital, London, when he distributed the prizes last Tuesday, Lord Wakefield referred to what he called a radical change in the relations between the doctor and his patients. "In my young days," he said, "the family doctor was somewhat prone to pronounce premature sentence of death. It was no uncommon thing to hear that so-and-so had been told that he had six months to live. This was, I suppose, part of the stern Victorian rigour of those days. We liked to face facts, but sometimes one can pay too high a price for this privilege. In many instances the patient outlived his sentence, to the satisfaction and delight of everyone—even including his doctor. There were other cases where the patient obediently faded away." Nowadays, on the other hand, it was usual to approach the subject of disease in a spirit of determined optimism ; the will to live was actively encouraged. By its discoveries, and by its own attitude to the tasks which face it, the medical profession had materially contributed to this great improvement, and in Lord Wakefield's opinion it was one of the triumphs of our time that medical science and psychology had been brought into fruitful contact.

Epsom College

The eighty-second annual general meeting of th
governors of Epsom College was held at 49, Bedford-squar
W.C., on Friday, June 21st. Lord Leverhulme, th
president of the College, was in the chair. The governo
received the names of the foundationers and pensione
elected by the conjoint committee, as well as details
the amounts granted to some of the unsuccessful applican
from the new Sherman Bigg Fund.

In presenting the report of the council for the pa
year the president paid a tribute to the prudence, for
sight, and efficiency of the retiring treasurer, Sir Willia
Hale-White, who during the ten years of his office had do
much for the College. In this relatively short space of th
the College had extended its benefits, got rid of its deb
enlarged and modernised its buildings, and increased
endowed fund. Turning to the work of the other memb
of the College council Lord Leverhulme spoke of the val
of the services so generously given by the chairman
the council, Sir Raymond Crawfurd, Dr. Henry Robins
chairman of the conjoint committee, Dr. Harold Spit
chairman of the executive committee, Dr. John Fawce
Mr. George E. Waugh, and Dr. Arnold Lyndon, dep
chairman of the executive committee for finance, sch
and selection matters.

On the motion of Sir William Hale-White, Dr. Jo
Fawcett was unanimously elected treasurer of
College in his place. The report was unanimously adop
and the proceedings ended with the passing of a wa
vote of thanks to Lord Leverhulme for presiding at
meeting. A list of the successful candidates appears
our advertisement columns (p. 51).

Middlesbrough Hospitals

A further stage in the development of Middlesbroug
public hospitals was reached on Saturday last when
Kingsley Wood, the Minister of Health, opened extensi
of the male surgical and tuberculosis wards at Holg
Municipal Hospital and a new cubicle block at West La
Hospital. At West Lane, where a new nurses' ho
was opened last October, every type of infectious dise
is treated except small-pox, and the new buildings inclu
an 8-bed puerperal fever block which is self-contain
The hospital can now accommodate 200 patients with
staff of 40. The Holgate Municipal Hospital was original
a poor-law institution, and with accommodation for 2
patients was transferred to the town council under t
Local Government Act of 1930. Dr. C. V. Dingle
medical officer of health for Middlesbrough, Dr. W. Brita
Jones medical superintendent of the Municipal Hospit
Dr. F. J. Henry tuberculosis officer, and Dr. G. B. Murr
deputy medical officer of health and resident medic
officer at West Lane.

Appointments

Baxter, C. B., O.B.E., M.B., F.R.C.S. Edin., has been appointe Surgeon to t[illegible]ospital, Reading.

Hooper, A. N., [illegible] Eng., Assistant Surgeon to the Royal [illegible]

Scott, Gordon, M.R.C.S., Resident Medical Officer, City of London Maternity Hospital.

Soden, G. E., M.R.C.S., Assistant Resident Medical Officer, City of London Maternity Hospital.

Royal Free Hospital.—The following appointments are announced :

McDowall, A., M.B. Edin., F.R.C.S. Eng., First House Surgeon ;

Sainsbury, H., M.R.C.S. Eng., Resident Anæsthetist ; and

Cobbe, C. J., M.R.C.S. Eng., Casualty Officer.

Vacancies

For further information refer to the advertisement columns

Accrington, Victoria Hospital.—H.S. £150.

Birmingham, Little Bromwich Hospital for Infectious Diseases.—Jun. Asst. M.O. £300.

Birmingham Maternity Hospital.—Res. M.O. and Registrar. £200.
